### Methods and Systems of PFAS Destruction using UV Irradiation at 222 Nanometers

---

#### Abstract

Methods, systems and devices for PFAS destruction including adding a sulfite salt to an aqueous solution containing PFAS and then irradiating the aqueous solution with light at 222 nm. The method may include adding a base to the aqueous solution in an amount sufficient to raise a pH of the aqueous solution including PFAS to about 10 or more. It may also include adding a halide salt such as a bromide salt or an iodine salt, and further adding a carbonate. Greater than 90%, or greater than 99%, of the PFAS in the solution may be destroyed by irradiating the aqueous solution in this way.

## Background/Summary

CROSS REFERENCE TO RELATED APPLICATIONS [0001] This application is a continuation of U.S. application Ser. No. 18/771,104, filed Jul. 12, 2024, titled Methods and Systems of PFAS Destruction using UV Irradiation at 222 Nanometers, which claims priority to the following: PROCESSES FOR EFFICIENT PHOTOCHEMICAL DESTRUCTION OF PFAS FROM WASTE STREAMS filed Jul. 14, 2023 U.S. Provisional Application No. 63/513,782; SYSTEMS AND METHODS OF PFAS DESTRUCTION filed Oct. 17, 2023 U.S. Provisional Application No. 63/591,040; and PRETREATMENT OF PFAS CONTAMINATED WATER PRIOR TO PHOTOREDUCTION filed Apr. 18, 2024 U.S. Provisional Application No. 63/635,938, the disclosures of all of which are hereby incorporated by reference.

## BACKGROUND

[0002] Per- and polyfluoroalkyl substances (PFASs) are a class of synthetically prepared compounds that have been used for decades in numerous consumer and industrial applications. PFASs have some unique surface properties and can also be both hydrophobic and oleophobic. As a result, PFASs are used as coating aids, lubricants, foaming aids and various surface treatments. They have proven especially useful as flame retardants in the form of aqueous film-forming foams (AFFF). Also, some PFASs are known to bio-accumulate in plants and animals. There is a growing body of evidence that exposure to PFASs can also cause a variety of health problems. Owing to these concerns, various world-wide regulatory agencies have started to establish strict limits to the presence of PFAS in food and water.

[0003] PFASs are a class of chemicals that contain perfluoroalkyl or polyfluoroalkyl groups. The definition and classification of PFASs has changed over time. PFASs are fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), i.e. with a few noted exceptions, any chemical with at least a perfluorinated methyl group (—CF<sub>3</sub>) or a perfluorinated methylene group (—CF<sub>2</sub>—) is a PFAS. Some of the most important examples of PFASs include the perfluorosulfonic acids (PFSAs), such as perfluorooctanesulfonic acid (PFOS) and the perfluorocarboxylic acids (PFCAs) like

perfluorooctanecarboxylic acid (PFOA). Fluorotelomers are fluorocarbon-based oligomers, or telomers, synthesized by telomerization. Some fluorotelomers and fluorotelomer-based compounds are a source of environmentally persistent perfluorinated carboxylic acids such as PFOA.

[0004] The persistence of PFASs, the health issues, and the regulatory landscape have prompted a great deal of research effort to reduce their presence in the environment. Much of the early work was focused on capture, for example from drinking water. However, more recently, there has been a stronger effort on the destruction of these materials. One of the attributes of PFASs is their resistance towards breaking down in the environment. PFASs are not easily metabolized by organisms, and do not decompose by exposure to visible light or longer wavelength UV irradiation typically found under terrestrial conditions.

[0005] Some of the methods that have proven effective for breaking down PFASs are supercritical water oxidation (SCWO) and treatment of PFASs in an aprotic polar solvent. SCWO works by heating water to 374° C. under high pressure (over 3000 psi). Therefore, SCWO is quite energy intensive and can suffer from clogging issues. The use of SCWO often requires wastes containing high solids because it relies on the heat capacity (btu) generated from this waste to make the process cost effective. An advantage of SCWO is its short residence time to be effective, on the order of 30 seconds to minutes. The use of basic aprotic media to destroy PFASs suffers from the fact that most waste streams are water-based and therefore not readily transferred to aprotic media that requires minimum water levels. In other cases, generating subcritical water conditions in alkaline environments has also been shown to destroy PFAS compounds. This process, referred to as hydrothermal alkaline treatment (HALT), operates at temperatures around 350° C. and pressures around 2400 psi.

[0006] Other processes for destroying PFASs involve the use of electrochemistry. Electrochemical destruction can destroy long chain PFASs (for example, PFOS and PFOA), however, shorter chain PFASs are less prone to destruction. It is speculated that the longer chained PFASs readily assemble on the electrodes and therefore can be readily oxidized or reduced. Other work has shown that sonication can result in PFAS destruction.

[0007] Improved processes are needed to efficiently and effectively destroy PFAS, particularly PFAS in water.

## SUMMARY

[0008] Various embodiments disclosed herein include methods systems and devices for PFAS Destruction using UV irradiation at 222 Nanometers. For example, some embodiments include methods of PFAS destruction including adding a sulfite salt to an aqueous solution containing PFAS, then irradiating the aqueous solution with light at 222 nm. The method may also include adding a base to the aqueous solution containing PFAS in an amount sufficient to raise a pH of the aqueous solution including PFAS to about 10 or more. The method may also include adding a halide salt to the aqueous solution including PFAS, such as a bromide salt or iodine salt. Some embodiments also include adding a carbonate to the aqueous solution including PFAS. The step of irradiating the aqueous solution may destroy greater than about 90% of the PFAS in the solution, or greater than about 99% of the PFAS in the solution. In some embodiments, the method also includes, prior to irradiating the aqueous solution containing PFAS, adding a persulfate and an acid or a base to the aqueous solution containing PFAS to increase or decrease the pH, then subjecting the aqueous solution containing PFAS to an increased temperature and pressure for a period of time sufficient for thermal oxidation. For example, the increased temperature may be about 100 to about 140 degrees Celsius and the increased pressure may be about 1 to about 5 bar.

[0009] Various embodiments include photoreactors for PFAS destruction including a reactor vessel configured to receive an aqueous solution containing PFAS and a first light source comprising an ultraviolet light source configured to deliver light at about 222 nm to the aqueous solution including PFAS in the reactor vessel. In some embodiments, the light source may be a krypton/chloride excimer lamp. The photoreactor may also include a second light or more sources

also positioned to direct light onto the aqueous solution in the reactor vessel, which may be identical to the first light source. In some embodiments, the reactor vessel may be a continuous reactor such as a stirred tank reactor vessel. Some embodiments may also include a source or sources of a sulfite salt and/or a halide salt configured to deliver the sulfite salt and/or halide salt to the aqueous solution upstream of or before entry into the reactor vessel or within the reactor vessel. Some embodiments may also include a source of base configured to deliver base to the aqueous solution upstream of or before into the reactor vessel or within the reactor vessel such that the aqueous solution has a pH of about 10 or more within the reactor vessel.

[0010] Other embodiments include systems PFAS destruction including a pretreatment reactor including a pre-treatment vessel configured to contain an aqueous solution containing PFAS at elevated pressure and comprising a heating element to heat the aqueous solution contained therein and sources of persulfate and acid or base configured to deliver persulfate and acid or base to the aqueous solution before or within the pre-treatment vessel and a photoreactor downstream of the pretreatment reactor. The photoreactor may include a reactor vessel configured to receive an aqueous solution, a plurality of ultraviolet light sources configured to deliver light at 222 nm to the aqueous solution including PFAS in the reactor vessel, and a source of a sulfite salt configured to deliver the sulfite salt to the aqueous solution before or within the reactor vessel.

[0011] Some embodiments include methods, systems and devices for oxidative pretreatment of aqueous solutions containing PFAS. For example, in some embodiments, methods of PFAS destruction include oxidatively pretreating an aqueous foam fractionate solution including PFAS to form a pretreated solution, the step of oxidatively pretreating the aqueous foam fractionate solution including mixing the aqueous foam fractionate solution with a persulfate and an acid or a base to increase or decrease the pH, then oxidizing the aqueous foam fractionate solution, then subjecting the pretreated solution to UV photolysis. UV photolysis may include directing UV light at 222 nm and/or 254 nm and/or 185 nm onto the pretreated aqueous foam fractionate solution. In some embodiments, oxidizing the aqueous foam fractionate solution may include subjecting the aqueous foam fractionate solution to an increased temperature and pressure for a period of time sufficient for thermal oxidation. For example, the increased temperature may be about 100 degrees to about 140 degrees Celsius and/or the increased pressure may be about 1 to about 5 bar. In some embodiments, oxidizing the aqueous foam fractionate solution includes subjecting the aqueous foam fractionate solution to ozone oxidation. In some embodiments, the method also includes, prior to and/or after oxidatively pretreating the aqueous foam fractionate solution, separating out solid particles from the aqueous foam fractionate solution.

[0012] In various other embodiments, methods of PFAS destruction mixing the aqueous foam fractionate solution with a persulfate and an acid or a base to increase or decrease the pH, subjecting the aqueous foam fractionate solution to a temperature of about 100 to about 140 degrees Celsius and pressure of about 1 bar to about 5 for a period of time sufficient for thermal oxidation, and subjecting the pretreated solution to UV photolysis at about 222 nm. The persulfate may be potassium persulfate, sodium persulfate, and/or aluminum persulfate, for example. The persulfate may be added to the aqueous foam fractionate solution to achieve a concentration of about 100 to about 200 mM in the aqueous foam fractionate solution. In some embodiments, the acid is mixed into the aqueous fractionate solution to reduce the pH of the aqueous foam fractionate solution, such as to between about 2 and about 4. In other embodiments, the base is mixed into the aqueous foam fractionate solution to increase the pH of the aqueous foam fractionate solution, such as to between about 10 and about 14.

[0013] Various other embodiments include systems for pretreatment of water containing PFAS including a pretreatment reactor comprising a pre-treatment vessel configured to contain water including PFAS at elevated pressure, the pretreatment vessel comprising a heating element to heat the water including PFAS contained therein, and a source of persulfate and acid or base configured to deliver persulfate and acid or base to the water including PFAS upstream of or within the pre-

treatment vessel. The system may also include a sedimentation tank upstream of or before and/or downstream of or after the pretreatment reactor. In some embodiments, the pretreatment reactor may also be a photoreactor and also include a source of UV light configured to direct UV light onto the water including PFAS after pretreatment. For example, the source of UV light may emit UV light at a peak of about 222 nm.

[0014] Other embodiments include methods, systems and devices for photo-electrochemical PFAS destruction. Various embodiments include photo-electrolytic devices for destroying PFAS including a photoreactor vessel configured to receive an aqueous solution including PFAS, a UV light source configured to direct UV light onto the aqueous solution including PFAS in the photoreactor vessel, a cathode within the photoreactor vessel and configured to contact the aqueous solution containing PFAS within the photoreactor vessel, an anode in an electrolyte solution, an electrical power supply configured to provide a voltage difference between the anode and cathode, and a membrane or ionic bridge between the anode and cathode. The UV light source may be a mercury lamp with emission peaks at approximately 185 nm and/or 254 nm or a krypton/chloride excimer lamp with an emission peak at approximately 222 nm, for example. In some embodiments, the UV light source may include a UV lamp within a quartz tube that is submerged in the photoreactor vessel. For example, the quartz tube may be located approximately 2 cm or less distance from the cathode. In some embodiments, the cathode may be a doped-diamond cathode. In some embodiments, the cathode may be a platinum, titanium and/or stainless steel electrode. In various embodiments, the cathode may include a mesh material. In some embodiments, the cathode may include a high surface area construction having an electrochemically active surface and a geometric surface area in which the electrochemically active surface area is greater than the geometric surface area. In some embodiments, the device may also include a source of inert gas connected to the photoreactor vessel and configured to bubble through the aqueous solution containing PFAS within the reactor vessel and/or through the anode electrolyte solution. In some embodiments, the photoelectric reactor vessel may be a continuous reactor such as a stirred tank reactor.

[0015] Other embodiments include photo-electrolytic devices for destroying PFAS including a photoreactor vessel configured to receive an aqueous solution including PFAS, a UV light source within a tube in the photoreactor vessel configured to direct UV light onto the aqueous solution including PFAS in the photoreactor vessel, a cathode within the photoreactor vessel and configured to contact the aqueous solution containing PFAS within the photoreactor vessel and located approximately 2 cm or less from the UV light source and having a high surface area construction with an electrochemically active surface area which is greater than the geometric surface area, an anode in an electrolyte solution, an electrical power source configured to provide a voltage difference across the anode and cathode, and a membrane or ionic bridge between the anode and cathode. The UV light source may be a mercury lamp with emission peaks at approximately 185 nm and/or 254 nm or a krypton/chloride excimer lamp an emission peak at approximately 222 nm, for example. In some embodiments, the photoreactor vessel may be a stirred tank reactor.

[0016] Other embodiments include methods for destroying PFAS in a photo-electrolytic device including providing water including PFAS to a photo-electrolytic device, photo-electrolytic device including a photoreactor vessel configured to receive the aqueous solution including PFAS, a UV light source, a cathode within the photoreactor vessel and contacting the aqueous solution containing PFAS within the photoreactor vessel, an anode in a cell containing an aqueous electrolyte, an electrical power source configured to provide a voltage difference across the anode and cathode, and a membrane or ionic bridge located between the anode and cathode, applying power from the electrical power source to create a voltage difference across the anode and cathode, and irradiating the water containing PFAS within the reactor vessel with the UV light. The steps of applying power and illuminating the water may occur as simultaneous or overlapping steps, for example. The method may also include continuously flowing the water containing PFAS through the photoreactor vessel. The method may include producing hydrogen gas at the cathode. In some

embodiments, the method also includes mixing the aqueous solution containing PFAS with an electrolyte and destroying the PFAS occurs without an addition of a sensitizer. In some embodiments, the method also includes mixing the aqueous solution containing PFAS with a sensitizer and an electrolyte. In some embodiments, the method also includes mixing the aqueous solution containing PFAS with a sulfite salt and a halide salt. In some embodiments, the method also includes mixing the aqueous solution containing PFAS with a halide salt and an electrolyte and applying a voltage across the anode and cathode which is sufficient to reduce the halogen to halide. For example, in some such methods, the halide is an iodide salt and the voltage applied across the anode and cathode is sufficient to reduce iodine to iodide. In some embodiments, the method also includes mixing the aqueous solution containing PFAS with a sulfite salt and an electrolyte and applying a voltage across the anode and cathode which is sufficient to reduce the sulfite radical anion or dithionate to the sulfite ion.

[0017] Various other embodiments include methods, systems and devices for nitrate removal in aqueous systems for improved PFAS destruction. Various embodiments include methods of PFAS destruction including removing nitrate from water containing PFAS, combining water containing PFAS with a sensitizer and a sufficient quantity of base to create a treatment solution having a pH of about 10 or more, and irradiating the treatment solution with UV light in a photoreactor to destroy a portion of the PFAS. In some embodiments, removing nitrate from the water containing PFAS includes electrolytically removing nitrate from the water containing PFAS. For example, in some embodiments, electrolytically removing nitrate includes electrolytically reducing nitrate to nitrogen gas and/or ammonia. The method may include contacting water containing PFAS with an electrode and applying current to the electrode. The electrode may be an iron, copper or iron:copper electrode, for example. The electrode may be a cathode of an electrolytic cell system which also include an anode in an aqueous electrolyte solution. In some such embodiments, the method may also include forming oxygen gas at the anode while reducing nitrate at the cathode. In various other embodiments, removing nitrate from the water containing PFAS may include filtration through a selective membrane. Examples of selective membrane which may be used include reverse osmosis, forward osmosis, nanofiltration (NF), and/or ultrafiltration (UF). In various embodiments, removing nitrate from water containing PFAS is a pretreatment step prior to irradiating the treatment solution. In various other embodiments, removing nitrate from water containing PFAS is a step that occurs within the photoreactor.

[0018] Various embodiments include method of PFAS destruction including contacting water containing PFAS with a cathode, applying current to the cathode to electrolytically reduce nitrate in the water containing PFAS, combining the water containing PFAS with a sulfite and a halide salt and a sufficient quantity of base to create a treatment solution having a pH of about 10 or more, and irradiating the treatment solution with UV light in a photoreactor to destroy a portion of the PFAS. In some embodiments the halide salt may be iodide and the UV light may be light with an emission peak at approximately 222 nm. In some embodiments, the method also includes oxidatively pretreating the water containing PFAS prior to irradiating the PFAS. In some such embodiments, oxidatively pretreating the water containing PFAS includes mixing the water containing PFAS with a persulfate and an acid or base and then subjecting the water to increased temperature and pressure.

[0019] Various embodiments include systems for the destruction of PFAS in water including a nitrate removal system configured to remove nitrate from water containing PFAS and nitrate including a selective membrane and/or an electrolytic cell system and a photoreactor including a reactor vessel configured to contain an aqueous solution and a source of ultraviolet light source positioned to direct light onto the contents of the reactor vessel. In some embodiments, the nitrate removal system may be located upstream before the photoreactor. In some embodiments, the nitrate removal system is an electrolytic cell system including a first cell including a cathode configured to contact the water containing PFAS in the first cell, second cell comprising an anode in an

electrolytic solution, a power source, and a salt brine and/or membrane separating the first and second cells. In some embodiments, the cathode is located within the photoreactor and the photoreactor vessel forms a container of the first cell. In various embodiments the cathode may include iron, copper and/or iron:copper, for example.

[0020] Other embodiments include methods, systems and devices for iodine capture from aqueous Solutions. Various embodiments include methods of removing iodide from an aqueous solution including submerging an iodophilic electrode in an aqueous solution containing iodide, applying a current to the electrode, and electrochemically oxidizing the iodide to iodine within the electrode. The method may also include adjusting the pH of the aqueous solution to between about 3 and about 8. In some embodiments, the step of applying the current creates a voltage of 0.3 V vs Ag/AgCl or greater. In various embodiments, the iodophilic electrode includes an iodophilic material and an electrically conductive material. For example, the iodophilic material may be cellulose, starch, cationic polymer, polyvinyl alcohol, polyethylene glycol, polypropylene glycol, polyvinylpyrrolidone, polypyrrole, polyaniline, poly(3,4-ethylenedioxythiophene), a metallocene, a metallocene-containing polymer, and/or a cationic metal complex. In some embodiments, the iodophilic electrode may also include a binder material. In some embodiments, the iodophilic material may include a starch, chitosan, or carboxycellulose. In some embodiments, the iodophilic material may be a cationic polymer. In some embodiments, the iodophilic material may be an anion exchange membrane. In some embodiments, the electrically conductive material may include graphite, graphene, carbon nanotubes, conductive polymers, or doped semiconductors and/or metals. In some embodiments, the binder may include polyvinylidene fluoride (PVDF), polyfluoroethylene (PTFE), styrenebutadiene rubber and/or polyamide. In some embodiments, the aqueous solution may be water after treatment by UV photolysis for the destruction of PFAS. In some such embodiments, the method may further include removing the electrode from the aqueous solution, then submerging the electrode in a second solution, then applying a current to the electrode to reduce the iodine and release it from the electrode in the form of iodide into the second solution.

[0021] Other embodiments include methods of capturing and recycling iodide from a photochemical advance reduction process (ARP) solution including receiving a photochemical ARP solution produced by an ARP process, adjusting a pH of the photochemical ARP solution to between about 4 and about 8, then contacting the ARP solution with an ion exchange media for a sufficient time for the ion exchange media to bind iodide, then contacting the ion exchange media with an aqueous salt solution to remove the bound iodide. In some embodiments, the ion exchange media includes a quaternary ammonium group. In some embodiments, the aqueous salt solution includes a mixture of water and sodium chloride, sodium bromide, potassium chloride, potassium bromide, sodium hydroxide, potassium hydroxide, sodium sulfate, and/or potassium sulfate. In some embodiments, the ion exchange media is a strong anion exchange media.

[0022] Other embodiments include systems for recovering iodine from an aqueous solution including an iodophilic electrode including an iodophilic material, a conductive material, a binder, and a current collector, in which the electrode is bonded to the current collector. In some such embodiments, the iodophilic material includes cellulose, starch, cationic polymer, polyvinyl alcohol, polyethylene glycol, polypropylene glycol, polyvinylpyrrolidone, polypyrrole, polyaniline, poly(3,4-ethylenedioxythiophene), a metallocene, a metallocene-containing polymer, and/or a cationic metal complex. In some embodiments, the conductive material includes graphite, graphene, carbon nanotubes, conductive polymers and/or doped semiconductors or metals. In some embodiments, the binder includes polyvinylidene fluoride (PVDF), polyfluoroethylene (PTFE), styrenebutadiene rubber and/or polyamide.

[0023] Other embodiments includes methods, systems and devices for recycling materials during PFAS destruction. Various embodiments include methods of PFAS destruction including a) providing water containing PFAS to a reactor vessel, b) irradiating the water within the reactor

vessel with UV light under conditions to destroy at least a portion of the PFAS to form treated water, c) passing the treated water through a selective membrane to form permeate and to form membrane reject comprising PFAS, d) providing the membrane reject back to the reactor vessel, e) providing additional water containing PFAS to the reactor vessel, wherein the membrane reject and the additional water containing PFAS are combined within the reactor vessel or before being provided to the reactor vessel, and f) irradiating the membrane reject and the additional water containing PFAS within the reactor vessel with UV light. The method may further include repeating the steps a plurality of times such that PFAS that is not destroyed is recycled through the reactor vessel. In some embodiments, the method also includes, before step b), adding a sensitizer to the water containing PFAS. In some such embodiments, the membrane reject also includes the sensitizer. In some such embodiments, the selective membrane may be a reverse osmosis or a nanofiltration membrane. For example, in some such embodiments, the selective membrane rejects at least about 99% of PFAS and sensitizer. In some embodiments, the method also includes adding additional sensitizer to the additional water containing PFAS or the membrane reject prior to step f). In various embodiments, the sensitizer includes a halide salt such as iodide, for example. In some embodiments, the method also includes, prior to step d), removing sulfate from the membrane reject. For example, removing sulfate includes adding calcium to the membrane reject to form a sulfate precipitate and separating the sulfate precipitate from the membrane reject. In some embodiments, the method also includes, prior to step d), passing the membrane reject through a water softener to remove calcium, magnesium and/or iron.

[0024] Various embodiments include method of PFAS destruction including a) providing water containing PFAS to a reactor vessel, b) adding a sulfite salt and a halide salt to the water containing PFAS to form a reaction solution, either before step a) or within the reactor vessel, c) irradiating the reaction solution with UV light in the reactor vessel under conditions to destroy at least a portion of the PFAS to form a treated solution, d) passing the treated solution through a selective membrane to form permeate and to form membrane reject comprising remaining PFAS and halide salt, wherein the selective membrane rejects greater than about 99% of the remaining PFAS and the halide salt present in the treated solution, and e) providing the membrane reject to the reactor vessel or to a separate reactor vessel. The method may further include discharging the permeate into the environment. In some embodiments, the steps may be performed continuously.

[0025] Other embodiments include systems for PFAS destruction including a photoreactor including a reactor vessel configured to receive water containing PFAS, a UV light source configured to direct UV light onto water containing PFAS within the reactor vessel, a selective membrane in fluid communication with, and downstream of or after, the photoreactor, the selective membrane selective for greater than 99% of PFAS present in the water containing PFAS after photolysis in the photoreactor, and means for fluid transport of membrane reject formed by the selective membrane to a location upstream of the photoreactor for further transport into the photoreactor or directly into the photoreactor. The selective membrane may be a reverse osmosis or nanofiltration membrane, for example. The system may also include a sedimentation system downstream of the selective membrane in line with the membrane reject outflow, before transport of the membrane reject to the photoreactor. In some embodiments, the system may also include a water softener downstream of or after the sedimentation system and before transport of the membrane reject to the photoreactor. In various embodiments, the reactor vessel may be a continuous reactor.

---

## Description

### BRIEF DESCRIPTION OF THE DRAWINGS

[0026] The following drawings are illustrative of embodiments and do not limit the scope of the

invention. The drawings are not necessarily to scale and are intended for use in conjunction with the following detailed description. Embodiments of the invention will be described with reference to the drawings, in which like numerals may represent like elements.

[0027] FIG. **1** is a schematic showing an example of an integrated system incorporating pretreatment, photolysis, and posttreatment according to various embodiments;

[0028] FIG. **2** is a schematic of an electrolytic cell according to various embodiments;

[0029] FIG. **3** is a schematic of an electrolytic cell for nitrate reduction according to various embodiments;

[0030] FIG. **4** is a method of integrating filtration and photodestruction according to various embodiments;

[0031] FIG. **5** is a flow chart of a process of PFAS destruction in a wastewater stream;

[0032] FIG. **6** is a flow chart of a process of PFAS destruction in a wastewater stream including thermal oxidation pretreatment;

[0033] FIG. **7** is a flow chart of PFAS destruction in a wastewater stream including ozone oxidation;

[0034] FIG. **8** is a representation of an example of a UV reactor as a photochemical portion of a treatment system;

[0035] FIG. **9** is a schematic of an alternative embodiment of a photo-electrolytic cell according to various embodiments;

[0036] FIG. **10** is the chemical structures of examples of polymers which may be used in various embodiments;

[0037] FIG. **11** are the chemical structures of further examples of polymers which may be used in various embodiments;

[0038] FIG. **12** shows examples of structures of polymeric n-type organic semiconductors that may be used in various embodiments;

[0039] FIG. **13** is a depiction of an example of the oxidation of disodium salt attached to a polymer according to various embodiments;

[0040] FIG. **14** is an example of the chemical structure polymers that may be used in various embodiments;

[0041] FIG. **15** is an example of the chemical structure of a polymer with oxidizable units that may be used in various embodiments;

DETAILED SUMMARY OF THE INVENTION

[0077] The systems and methods described herein relate to processes for the photochemical destruction of PFASs. More specifically, the systems and methods relate to a class of UV photochemical destruction referred to as Ultraviolet-based advanced reduction processes (UV-ARP). The UV-ARP method is based on generating a highly reducing species, such as solvated electrons, produced by the irradiation of a photosensitizer. The photosensitizer or sensitizer absorbs UV energy and generates a solvated electron and an oxidized sensitizer species. The solvated electrons can react with a PFAS molecule.

[0078] Various embodiments include processes to increase the efficiency of the photochemical destruction of PFAS and allow photochemical methods to be more generally used on a variety of PFAS-containing waste streams. Other embodiments include UV photolysis reactor designs to accomplish more efficient destruction of PFASs. Still other embodiments include systems and methods for recovering high value materials following UV photolysis of PFAS materials. Other embodiments include systems and methods for additional treatment of waste streams after UV photolysis and prior to release into the environment or for reuse in an industrial application.

[0079] Various embodiments include photochemical destruction of PFASs as a method to destroy the so-called “Forever Chemicals”. In some embodiments, the photochemical system includes a reactor vessel with one or more UV light sources. The reactor may be charged with a liquid consisting of one or more PFAS, water (or another solvent), and sensitizers capable of absorbing UV light and producing a reactive species. In addition, there optionally may be one or more other chemical additives to promote the reaction. The process, systems and methods disclosed herein result in improved efficiencies, lower costs, and use of less chemicals. In some embodiments, the materials used in the process may be recycled and reused, further increasing efficiency and lowering costs. A further embodiment is to treat the photolyzed solution such that the solution can be recycled, further purified or disposed of.

[0080] Various embodiments include the use of ultraviolet-based advanced reduction processes (UV-ARP) which may be effective for the treatment of several classes of recalcitrant chemical contaminants in water. Advanced reduction processes are based on the production of highly reducing hydrated electrons which exhibit fast bimolecular reaction rate constants with inorganic and organic compounds. In UV-ARP, solvated electrons may be produced by the illumination of sensitizers capable of generating a solvated electron when irradiated with a UV light source. Photoproduced solvated electrons, produced by the systems and methods describe herein, can react with PFASs and other pollutants, leading to the destruction of the PFAS.

[0081] A result of UV-ARP is the mineralization of the PFASs by converting the carbon-fluoride bond to the fluoride ion and carbon species, such as acetate, formate, carbon dioxide, shorter chain PFAS molecules, other polyfluorinated molecules, and/or carbonate. In this context, mineralization means reduction of the carbon-bound fluorine on PFAS to the fluoride ion  $F^{sup.-}$ .

[0082] In some embodiments, the UV-ARP method may be used to treat PFAS present in wastewater or other water sources directly, such as in a high throughput treatment system. In other embodiments, the UV-ARP method may be used to treat PFAS which has been extracted or absorbed and isolated and/or concentrated from the environment, such as from wastewater or other water sources. This PFAS may be suspended or dissolved into an aqueous solution for use in the UV-ARP methods and systems described herein.

[0083] The methods and systems of PFAS destruction described herein include the ability to destroy PFAS contaminants, including carboxylated and sulfonated PFAS contaminants. Examples of PFAS which may be destroyed by the embodiments described herein include but are not limited to Trifluoroacetic Acid (TFA), Perfluorobutanoic acid (PFBA), perfluoropentanoic acid (PFPeA), Perfluorohexanoic acid (PFHxA), Perfluorooctanoic acid (PFOA), Perfluorobutanesulfonic acid (PFBS), Perfluorohexanesulfonic acid (PFHxS) and Perfluorooctanesulfonic acid (PFOS). More than one type of PFAS may be treated and destroyed simultaneously using the photoreaction methods described herein.

[0084] Destruction of the PFAS includes a change in the identity of the target chemical pollutant through the cleavage of chemical bonds. Destruction that yields complex chemical compounds as final products is referred to as degradation. Destruction includes removing one or more chemical groups to reduce or eliminate toxicity.

[0085] The PFAS used in various embodiments may be in aqueous solution, such as PFAS present in a water from a contaminated natural source or other source or may be concentrated by a prior capture or pretreatment method or other treatment method.

[0086] Some embodiments include an electrochemical system to convert the photochemical byproducts back to the original sensitizer and to prevent the build-up of significant concentrations of species that scavenge solvated electrons.

[0087] There are relatively few processes for destroying PFASs compared to other pollutants. Since photolytic generation of solvated electrons is one of these methods, it is beneficial to minimize possible interferences with the photochemical process. Therefore, it may be desirable in some cases for the waste stream to be pre-treated, using other processes, to allow the photolysis reaction to proceed with maximum efficiency. Furthermore, the photolysis reaction to efficiently generate solvated electrons may require very alkaline conditions, such as a pH greater than 10 or greater than 12. In addition, other inorganic salts may be added to scavenge photoproducts and minimize the concentration of molecular oxygen. As a result, the concentration of inorganic ions can be quite high. The destruction of PFASs also produces the inorganic fluoride anion ( $F^{sup.-}$ ). In order to dispose of the waste stream following photolysis, it therefore may be desirable to reduce the concentration of potentially corrosive species or other unwanted species. Also, even though photolysis can remove greater than 90% and often more than 99% of the PFASs, it may still be beneficial to use other separation techniques to further lower the PFASs concentration, such as to comply with regulatory limits or to decrease reactor time. Many of these processes, for example ion exchange technology, reverse osmosis, or granular activated carbon (GAC) beds which would be used to further decrease the PFAS concentration, may be negatively impacted by the presence of competitive ionic species. Therefore, to effectively deploy these technologies it may also be beneficial to decrease the ionic loading.

[0088] For at least these reasons, an effective system for photochemically destroying PFASs may consist of the following steps: pretreatment, then photolysis, then post-treatment, then optionally a polishing step. Different systems and methods may be employed for each of these steps, in various combinations. While all of the steps may be used in many cases, in other cases a system of methods may not include all of these steps. Furthermore, the systems and embodiments may further include means for fluid transportation including pipes, pumps, valves, inlets, outlets, etc., such as to connect various components and connect to and from inlets and outlets of various components. An example of an integrated system incorporating pretreatment, photolysis, and post-treatment is shown in FIG. 1.

#### Pretreatment Step(s)

[0089] Various embodiments successfully implement UV-ARP by minimizing the time for photochemical destruction of the PFAS and minimizing the cost of reagents, including through the use of pretreatments.

[0090] PFASs are found in many waste streams. Some common PFAS-containing waste streams that may be treated according to various embodiments include effluent from industrial producers of PFASs, effluent from textiles plants, foam fractionation concentrates, Aqueous Film-Forming Foams (AFFF), AFFF rinsates, landfill leachates, contaminated ground water, municipal water waste streams, and pot still bottoms. Some of these waste streams may be amenable to simple pretreatment protocols such as filtering. Other waste streams may require unique pretreatments, such as removal of solvated electron scavengers, scattering materials, or UV absorbers. In some cases, such as where the composition of a waste stream is known, and the nature of the non-PFAS species is understood, the pre-treatment step can be omitted. One or more pretreatment systems and

methods as described herein may be used in various embodiments.

[0091] Solvated electrons react with a variety of chemical species naturally present in water. Any photochemical system that uses solvated electrons to react with PFASs can be sensitive to other chemical species in the waste stream. These other chemical species can scavenge the solvated electrons. In fact, many common chemical pollutants react faster with solvated electrons than PFAS. Depending on the concentration and nature of these chemical species, the solvated electrons may preferentially react with these materials until such times that these species are consumed. This can result in substantially longer reaction times to destroy the PFASs.

[0092] Therefore, in various embodiments, these contaminants may be preferentially consumed before the targeted PFAS. In some cases, the contaminants are present in sufficient quantities such that PFAS destruction would not occur, or would occur very slowly, such as over days or weeks. Nitrates are an example of a common contaminant in wastewater that will readily react with solvated electrons and reduce UV efficiency. There are two reasons that nitrate may interfere with the photochemical destruction of PFASs: 1) nitrate is an efficient scavenger of electrons, 2) nitrate has strong absorption of light in the UV part of the electromagnetic spectrum. Since UV photolysis is one of processes that can destroy PFASs under ambient conditions, and other contaminants can be efficiently removed by other processes, a pre-treatment step may be used to remove these contaminants.

[0093] Various embodiments disclosed herein include systems and methods of oxidative pretreatment of waste streams including PFAS prior to UV photoreduction. The pretreatment processes may include oxidation processes including thermal oxidation and/or ozone oxidation treatment. In some embodiments, thermal oxidation treatment may include mixing the wastewater with a persulfate such as potassium persulfate or sodium persulfate as well as a base or acid to increase or reduce the pH of the wastewater and treating the wastewater at elevated temperature and/or pressure. In some embodiments, the ozone treatment includes mixing the wastewater with a base to increase the pH of the wastewater followed by ozone treatment. After pretreatment, UV photoreduction of the wastewater may be more efficient, with a higher percentage of reduction of PFAS achieved following the photoreduction. For example, the thermal oxidation treatments disclosed herein result in a much more efficient PFAS destruction using UV photoreduction at 222 nm, requiring much less dilution and, therefore, making the photoreduction process much more efficient and cost effective.

[0094] Pretreatment is beneficial because, in addition to the PFAS targets of UV photoreduction, waste streams may include other components which inhibitor interfere with photoreduction. Some of these components may interfere with light transmission, making UV-based PFAS destruction process less effective. Others may interfere with the chemical reactions occurring during UV photoreduction. Various embodiments include methods of reducing or eliminating the presence of these components, enabling more efficient subsequent PFAS photoreduction. The pretreatment processes described herein may remove solvated electron scavengers, scattering materials and/or UV absorbers. The process and systems increase the efficiency of the photochemical destruction of PFAS, allow photochemical methods to be more generally used on a variety of PFAS-containing waste streams, and decrease the time required for PFAS destruction as well as the expense.

[0095] Pretreatment may improve light transmission, enabling the UV light to penetrate the wastewater more thoroughly. At the same time, the pretreatment may not interact with the PFAS substances or remove them from the water component of the wastewater. In this way, the PFAS component of the wastewater is not split during the pretreatment, which would then require treatment of not only the liquid component of the wastewater but also the PFAS which was separated from the liquid component of the wastewater, increasing the complexity and the cost. The pretreatment is not expected to result in defluorination of the PFAS but might alter the PFAS (such as a telomer) to another PFAS that is easier to photoreduce. However, the main purpose of the pretreatment is to interact with, alter, or remove non-PFAS components of the waste stream, which

might otherwise interfere with the subsequent UV reduction. Furthermore, the pretreatments do not produce chemical products which interfere with or reduce the efficiency of the UV photoreduction process. The pretreatments disclosed herein result in a waste stream that is more amenable to UV photoreduction and therefore more efficient due to increased light transmission without a separation of the PFAS and without the creation of interfering substances.

[0096] Challenges for the successful implementation of UV photoreduction of PFAS in wastewater include maximizing the destruction performance, minimizing the time for photochemical destruction and minimizing the cost of reagents. The pretreatments disclosed herein result in a more efficient UV photoreduction, with less dilution of the waste stream. As a result, the process requires less volume and, overall, less reagents.

[0097] Another issue with using UV-ARP is that the sensitizer cost tends to dominate the bill of materials. Therefore, a practical and efficient method to recover the sensitizer or sensitizer precursor is desired.

[0098] In some cases, the compositions of the waste streams are well understood, and steps can be taken to reduce potential scavengers. This might be the case for industrial waste streams where the reactants and products are known. In other cases, various embodiments may characterize the waste stream, such as by one or more analytical techniques such as mass spectrometry, gas chromatography mass spectroscopy, multinuclear NMR, infrared spectroscopy, and/or UV absorption spectroscopy. The determination of concentrations and the chemical composition allow for the waste stream to be treated prior to UV photolysis. Pre-treatment of the waste streams prior to the UV photolysis may result in substantial reduction in the time to destroy the PFASs.

[0099] In some embodiments, treatment may occur between multiple photoreactors in series as an intermediate step. For example, photolysis may be performed in a first reactor. The waste stream may then be further processed in a second reactor (or more additional reactors in series) which might employ different treatment conditions than the first reactor, such as different wavelengths of light, sensitizers, pH, temperature, etc.

[0100] In some embodiments, multiple pretreatment steps may be employed before the photolysis process. For example, a clarification step may be used, such as between a pre-treatment process and the photolysis process, which may allow for settling and separation of solids out of the wastewater.

[0101] For removal of contaminants that scavenge active photochemical species, multiple techniques may be employed. For example, nitrate and nitrite may be particularly problematic impurities in the UV-ARP and may be reduced or removed in various embodiments prior to UV treatment. Other water impurities that also scavenge solvated electrons, and that may be removed by pretreatment in various embodiments, include but are not limited to the following: 1) organic impurities such as chlorinated organic compounds (COCs) including: chlorinated biphenyls, chlorinated dibenzodioxin, chloroform, tetrachloroethylenes and other chlorinated solvents and cleaning fluids, 2) halogen oxides: OCl.sup.-, ClO.sub.2.sup.-, ClO.sub.3.sup.-, ClO.sub.4.sup.-, OBr.sup.-, BrO.sub.2.sup.-, BrO.sub.3.sup.-, BrO.sub.4.sup.-, IO.sup.-, IO.sub.2.sup.-, IO.sub.3.sup.-, IO.sub.4.sup.- or their corresponding conjugate acids.

[0102] One method of managing impurities that interfere with UV treatment is to have them consumed as part of the ARP. In such cases, such as with nitrates, the impurities may be consumed before the PFAS, during an induction time before the PFAS destruction occurs. However, there are wastewaters that are contaminated with very high levels of impurities such as nitrates, for example, near water sources that are associated with intense agricultural activity. In these cases, the nitrate levels can exceed 400 mg/Liter (400 ppm). It is not uncommon for these waste waters to be further concentrated by using other techniques, such as reverse osmosis or the use of solvent extraction methods on adsorbent media (e.g., in pot still bottoms), to levels of 20,000 ppm or higher. In PFAS samples with these levels of nitrate PFAS destruction is not just delayed but ineffective (less than 5% over a twenty-four-hour period of UV photolysis). In such cases, alternative methods of pretreatment such as those described herein may be particularly useful.

[0103] In various embodiments including catalytic systems, the catalyst may be put on a support and configured such that the water to be treated is allowed to flow over the catalyst and support. For example, for nitrate reduction with hydrogen using a noble metal as a catalyst, can result in the production of  $\text{NH}_4^+$ . Moreover, when hydrogen gas is used,  $\text{H}^+$  is a byproduct, which may cause the pH of the system to be lowered. Therefore, in various embodiments, a base may be added to compensate for these changes.

[0104] In some embodiments, hydrogen gas may be used as a reductant. For example, hydrogen gas may be bubbled through the solution or electrochemically generated and used in conjunction with a catalytic system as described above as a pretreatment that could be used to eliminate non-PFAS pollutants. Various embodiments may include a mono-metallic system, while other embodiments may include bimetallic catalysts for selectively reducing. Examples of bimetallic metal catalysts which may be used in various embodiments include a first metal such as a noble metal like Pd or Pt and a second metal (promoter metal) such as Cu, Sn or In. Although combinations may also be used, such as bimetallic catalysts in which the first metal is Rh, Ru or Ir and the second metal (promoter metal) is Ni, Ag, Zn or Fe.

[0105] Halogen oxides, like bromate, are also catalytically reduced by many metals including Pd, Pt, Ir, Rh, Ru, Fe, Sn, Cu, Zn and Ni supported on activated carbon and hydrogen gas at room temperature and pressure. All these catalysts are active in the conversion of bromate into bromide. Ruthenium, palladium, platinum and rhodium were the most efficient; platinum showed the best activity. The halogen oxides can also be electrochemically reduced. An organometallic rhenium catalyst deposited on a  $\text{TiO}_2$  reactive electrochemical membrane was effective in electrocatalytically reducing aqueous  $\text{ClO}_4^-$  to  $\text{Cl}^-$ . The sulfite ion can also reduce the number of halogen oxides to benign species like halides.

[0106] Electrochemical pretreatment. In some embodiments, pretreatment of the waste stream may be performed using electrochemistry. Because electrochemistry may breakdown only longer-chain PFASs (for example, PFOS or PFOA), it may not constitute an efficient solution to total PFAS destruction. However, in various embodiments, electrochemistry may be used as a pretreatment step to partially react PFASs to a form that is susceptible or more susceptible to the subsequent UV-ARP process. In this regard, pre-reacting various telomers, for example, may significantly reduce the photolysis time and maximize the efficiency of the process.

[0107] Nitrate pretreatment. Various embodiments include pretreatment of a waste stream to remove nitrate and nitrite. One or more methods may be used including chemical reduction, ion exchange membranes, electrodialysis, electrochemical reduction, photochemical reduction, and bioremediation wherein nitrate or nitrite are degraded by an organism. Although in principle any of these methods could be effective, a key consideration is to minimize the formation of potential products that might efficiently scavenge electrons, for example other nitrogen oxides, or those which have absorption transitions in the UV that might reduce the amount of light that can be absorbed by the sensitizer. If the concentration of potentially interfering chemical species has been determined, chemicals can be added that transform these contaminants into materials that do not react with or react less readily with solvated electrons.

[0108] In some embodiments, pretreatment to reduce or remove nitrate may include the reduction of nitrate to molecular nitrogen or ammonia. For example, in acidic solutions, nitrate may be reduced as a pretreatment, for example, by formic acid, iron metal or zero-valent iron, aluminum-iron alloys, methanol and ammonium ion. In basic solutions, nitrate may be chemically reduced as a pretreatment by constituents that include but are not limited to aluminum powder, zinc and iron metal or zero-valent iron,  $\text{Fe}^{2+}$ , ammonia, hydrazine, glucose, hydrogen and thiosulfate, for example. In some embodiments, a suitable catalyst may be used to help accelerate these reactions. Example of a suitable catalysts which may be used in various embodiments include palladium on carbon.

[0109] In some embodiments, the photochemical processes may be utilized, alone or in

combination with pretreatment, for the reduction of nitrate. For example, in some cases, the addition of an inorganic photocatalyst like titanium dioxide, iron, or manganese may be used in a photoreactor to selectively reduce and remove nitrate and nitrite prior to the addition of a hydrated electron generating species for the reduction of PFAS. In other embodiments, an organic acid or base including, but not limited to, oxalic acid and/or formate may be added to a photochemical reactor and treated under UV light as a means of removing nitrate. Inorganic and organic photocatalysts may be used in combination in a separate UV reactor or a same UV reactor as the PFAS reduction.

[0110] Some embodiments may use an electrochemical process for reduction of nitrate and other contaminants to treat nitrate or nitrite in water. For example, the methods may use a system including three components: 1) a cathode where reduction takes place, 2) an anode where oxidation occurs, and 3) an electrolyte solution which is capable of supporting ion transport.

[0111] Various embodiments may include the electrochemical reduction of nitrate to nitrogen gas and may involve numerous reactions, products, and intermediates (e.g., ammonia, nitrite, hydrazine, hydroxylamine, nitric oxide, and nitrous oxide). However,  $\text{N}_2$  and  $\text{NH}_3/\text{NH}_4^+$  are the thermodynamically most stable forms of nitrogen under standard conditions. Electrochemical nitrate reduction according to various embodiments may be described by the following reactions:

[0112] Both above reactions are multi-electron transfer processes. Several factors, such as electrode material or crystal plane, may be modified or adjusted to determine the final products of electrochemical reduction of nitrate. For example, various embodiments may employ a catalyst and/or electrode material or other conditions selected to produce molecular nitrogen as a reaction product.

[0113] In some embodiments, electrochemical reduction of nitrogen may include the use of monometallic catalysts of noble metal (such as Ru, Rh, Pd, Ag, Pt, Au, etc.) and/or first-row transition metal systems. For example, some first-row transition metal systems which may be used in various embodiments show a high catalytic selectivity for electrochemical reduction of nitrate, effective removal, and low cost, including iron or copper metal foams, Cu nanosheets, Cu on 3,4,5,9-perylenetetracarboxylic anhydride, cobalt nanoarrays among others. In some embodiments, two-component metal catalyst systems such as Pt- and Pd-based catalysts modified by introducing modifier metals (Sn, Cu, Bi, and Ge) onto the electrode surface may be used and may result in higher nitrate reduction activity. Other bimetallic catalysts which may be used in various embodiments include Cu/Fe systems, Pt<sub>78</sub>Ru<sub>22</sub> on Carbon, Cu<sub>50</sub>Ni<sub>50</sub>. In still other embodiments, electrochemical reduction of nitrate may include the use of metal oxide catalysts such as NiO porous nanoplates on Co<sub>3</sub>O<sub>4</sub>, nanotube heterostructure of Co/CoO nanosheet arrays with Schottky interfaces on nickel foams, Cu/Cu<sub>2</sub>O nanowire arrays, TiO<sub>2-x</sub>, or TiO<sub>2</sub>.

[0114] In some embodiments, electrochemistry may be performed as a pretreatment to reduce nitrate using an iron cathode. For example, in various embodiments, the electrode may be used under constant reductive bias to limit the formation of  $\text{Fe}^{2+}$  or  $\text{Fe}^{3+}$  which could dissolve, causing corrosion of the electrode. The solutions may be modified, such as by the addition of base, or maintained within the basic range, such as a pH range of greater than about 10, or about 10 to about 12, for example, to limit the dissolution of iron that can occur in acidic conditions. A voltage in the range of  $-1.0$  to  $-1.5$  V vs Ag/AgCl may be applied to the iron electrode. Higher voltages may be used, but they could result in decreased selectivity for nitrate reduction due to increasing water reduction. The electrolysis should be continued until the desired nitrate

concentration is reached.

[0115] In some embodiments, electrochemistry may be performed as a pretreatment to reduce nitrate using a copper cathode. For example, in various embodiments, the electrode may be used under constant reductive bias to limit the formation of  $\text{Cu}^{\text{sup.}+}$  or  $\text{Cu}^{\text{sup.}2+}$  which could dissolve, causing corrosion of the electrode. The solution may be modified or maintained to be within the pH range of about 2 to about 12, for example. In some embodiments, the pH may be modified, such as by the addition of acid, or maintained within the acidic range, such as less than about 4, or between about 2 and about 4, as ammonia is the primary product of nitrate reduction in acidic conditions, and ammonia does not interfere with the ARP. In basic conditions nitrite is the primary product of nitrate reduction, and nitrite could interfere with the ARP. In the acidic condition, a voltage in the range of  $-0.6$  to  $-1.0$  V vs Ag/AgCl may be applied to the copper electrode. Higher voltages could result in the formation of nitrite instead of ammonia and may be avoided. The electrolysis should be continued until the desired nitrate concentration is reached.

[0116] In some embodiments, electrochemistry may be performed as a pretreatment to reduce nitrate using a copper:iron cathode. The electrode may be under constant reductive bias to limit the formation of  $\text{Cu}^{\text{sup.}+}$ ,  $\text{Cu}^{\text{sup.}2+}$ ,  $\text{Fe}^{\text{sup.}2+}$ , or  $\text{Fe}^{\text{sup.}3+}$  which could dissolve, causing corrosion of the electrode. The solution may be modified, such as by the addition of base, or maintained to be in the basic pH range, such as a pH of greater than about 10, or a pH of between about 10 and about 12, to limit the dissolution of iron that may occur in acidic conditions. A voltage in the range of  $-1.3$  to  $-1.4$  V vs Ag/AgCl may be applied to the Cu:Fe cathode. This is sufficient to effectively reduce nitrate and nitrite to nitrogen gas, while limiting the competition from water reduction. The electrolysis should be continued until the desired nitrate concentration is reached.

[0117] Electrochemical systems may be utilized prior to or simultaneous with UV irradiation. An example of an electrochemical system that may be used in various embodiments described herein, such as prior to UV irradiation including during various pretreatment processes, is shown in FIG. 2. The containers that the anode or cathode are placed in might also be referred to as the anode compartment and cathode compartment, respectively. A system like the one shown may be used for pretreatment to reduce nitrate as discussed above, for example. The system may also be used in post treatment steps to recover valuable reagents such as a sensitizer. The electrolytic cell as shown is an electrochemical device that uses an external power supply to provide electrical energy to drive chemical reactions that would not occur without the application of electrical energy. The electrical energy establishes a voltage difference between two electrodes which are immersed in an electrolyte. The electrolyte may be a solvent with dissolved salt or salts. For example, in many embodiments, the solvent is water and the salts are inorganic salts like sodium chloride, sodium bromide, sodium iodide, potassium chloride, potassium bromide, sodium sulfate and/or potassium sulfate. However, in various embodiments described herein, some salts like sodium nitrate, potassium nitrate, sodium perchlorate and potassium perchlorate may interfere with the photochemical reaction because they react with solvated electrons and therefore these salts may be excluded from use as electrolytes. In various embodiments including aqueous solutions, the concentration of electrolytes may be between about 0.01 M to 1.0 M, or at least about 0.1 M, such as between about 0.1 M and about 1.0 M, to allow migration of the charges.

[0118] In the example electrolytic cell shown in FIG. 2, the system includes two electrodes, an electrical power supply, electrolyte, and inert gas that can be bubbled through the system. The electrodes are in separate compartments that are connected by a membrane or a salt bridge, also known as an ion bridge. The salt bridge or membrane serves several important functions including maintaining electrical neutrality, stabilizing the junction potential, and minimizing cross-contamination. A typical membrane used in this device is a cation exchange membrane. Examples of cation exchange membranes that may be used include, but are not limited to, perfluorinated or partially fluorinated polymers, such as Nafion. In alternative embodiments, the electrodes could be in the same compartment. Although not shown, in various embodiments the electrolyte may be

stirred in both chambers, such as by a mechanical stirrer or a magnetic stirrer including a magnet in the chamber with the cell on top of the magnetic stirrer. In this electrolytic cell configuration, the reaction products formed at each electrode are separated. In some cases, this is useful because some of the products can interfere with the desired reactions. Although FIG. 2 shows a single electrode in the anode and cathode compartments, multiple electrodes can be placed in these compartments. These electrodes could be the same material or a different material.

[0119] FIG. 3 is an example of an electrolytic system which may be used for nitrate reduction according to various embodiments. In the example, the electrolytic cell is a divided 2-electrode nitrate/nitrite reduction electrolytic cell. A nitrate/nitrite solution and a separate electrolyte solution are divided by a cation exchange membrane. Both solutions are purged with an inert gas, such as argon. A cathode is placed in the nitrate/nitrite solution and an anode is placed in the other electrolyte solution. A voltage is applied between the cathode and anode to cause the reduction of nitrate/nitrite to  $\text{N}_2$  at the cathode and a sacrificial oxidation reaction at the anode. The oxidation reaction occurring at the anode could be water oxidation to form  $\text{O}_2$ . In another embodiment a sacrificial electron donor, such as sodium sulfite, could be added to lower the voltage requirement of the cell.

[0120] In some manifestations, the electrode systems could be used in a compartment that is separate from the photolysis chamber. For example, some embodiments may have an electrochemical system that removes impurities like nitrate and nitrite separate from the photolysis chamber so that wastewater could be scrubbed of these impurities while simultaneously photolyzing pre-purified water. For example, a system may include a first chamber in which pre-treatment occurs and a second chamber in which photolysis occurs. The system may have additional chambers as well. After photolysis of a first batch of wastewater is complete, the treated wastewater could be removed from the photolysis chamber and pretreated solution could be transferred from the pretreatment chamber to the photolysis chamber. The pretreatment chamber could then be refilled with wastewater, such as PFAS contaminated water, for pretreatment. In this way, pre-treatment and photolysis may be occurring at the same time but in separate chambers.

[0121] In some embodiments the post-electrolysis solution may be run through a cation exchange resin before the ARP. In this way, any cations that are present in the solution due to dissolution of the nitrate reduction cathode, which will be detrimental to the ARP, can be exchanged for Na or K, which will not be detrimental to the ARP.

[0122] Filtration pretreatment. Various embodiments may include pretreatment filtration of the wastewater. For example, FIG. 4 presents a schematic demonstrating potential pathways to implement membrane-based separation technologies such as reverse osmosis (RO), nanofiltration (NF), ultrafiltration (UF), ultrafiltration, microfiltration, forward osmosis, and/or electrodialysis prior to photoreduction to improve water throughput and defluorination performance. In some embodiments, the process begins by concentrating the PFAS in the contaminated wastewater with a pre-treatment filtration through one or more membrane systems: RO, NF, and/or UF, for example. The membrane reject solution, also called the concentrate, includes the materials which do not pass through the membrane, such as the large PFAS molecules whose molecular weight is above half of the molecular weight cut-off (MWCO). As a result, the concentration of PFAS increases in the membrane reject the solution, while the water that passes through the membrane is free of or contains only trace levels of PFAS compounds. After filtration of the wastewater, the membrane reject solution may be further filtered one or more additional times by passing the rejection solution through the same membrane system again and/or a different membrane system. The membrane reject solution with a higher than initial concentration of PFAS may then undergo photoreduction. Following photoreduction treatment, the solution may optionally be filtered again through one or more membrane systems to remove remaining PFAS compounds in the effluent. The subsequent filtration process is also helpful for recovering the chemicals used in the destruction process (e.g., recirculating concentrated rejects back to photoreactor). This filtration process may be used in any

of the variety of systems and methods of PFAS destruction as described herein. Additionally, other types of filtration media or membranes may be used to selectively concentrate and isolate PFAS from background constituents. For example, an alternative pore size membrane with macro or nano-sized pores could be used to selectively isolate PFAS into the reject solution while allowing anions such as nitrate, chloride, or sulfate to pass through the membrane to the permeate.

[0123] Organics pretreatment. Other contaminants that may inhibit UV-ARP processes are those that inhibit the transmission of UV light into a water stream. These include but are not limited to organic substances like humic acid, particulate matter/suspended solids, and UV absorbing inorganic species like iron. These contaminants may also be reduced in concentration or removed by pretreatment according to various embodiments.

[0124] For removal of UV inhibiting substances, multiple techniques may be utilized. For the removal of solids, techniques include but are not limited to flocculation, coagulation, clarification, filtration, centrifugation, and sedimentation. For the removal of organic constituents, pre-treatments such as chemical oxidation, including but not limited to photochemical, chemical, ozonolysis or electrochemical oxidation processes, may be utilized. In addition, biological or hydrothermal treatments may be utilized in various embodiments. Oxidative species that may be used include but are not limited to ozone, hydrogen peroxide, persulfate, and permanganate species.

[0125] Reagent pretreatment. In various embodiments, the method of pretreatment may include adding reagents that are used in the UV-ARP and results in byproducts that do not interfere with the UV-ARP reaction. For example, sulfite may be added as a pretreatment to reduce or eliminate oxyhalides contaminants. The byproducts of this reaction are halides and sulfate ions which minimally affect the UV-ARP.

[0126] Metal complex pretreatment. Another class of solvated electron scavengers which may be removed by pretreatment in various embodiments is metal ions or metal complexes. Heavy metals are being found in increasing levels in wastewater, including zinc, mercury, nickel, chromium, and arsenic, which cause concern for human health. The increased presence of these species is the result of industrial activity (e.g. plating, battery manufacture and disposal, textiles, petrochemical and paper manufacturing). Wastewater may also contain silver, iron and manganese, calcium, molybdenum, antimony, arsenic, and cobalt. Various embodiments include methods and systems to remove these species including electrocoagulation, adsorption treatments, using synthetic and/or natural absorbents, membrane treatments, chemical treatments, electrical treatments and photocatalytic treatments. The adsorption treatments may include carbon-based absorbents including one or more of the following: activated carbon, carbon nanotubes and graphene, and in some embodiments, other chemical species may be grafted to the carbon treatments. Other absorbents which may be used in various embodiments include chitosan, various minerals such as micas, clays, and zeolites, magnetic adsorbents where a magnetic nanoparticle is attached to an absorbent species, and metal-organic framework materials. For example, the treatment solution could be run through a column or bed to remove scavengers. Alternatively, reagents could be added to the treatment solution to cause precipitation, coagulation, or flocculation. This could be followed by settling and removal of the clear solution such as by decanting or siphoning. In other alternatives, the solids could be removed by passing the solution through a filter. Membranes are also used to remediate metal contamination in various embodiments. Membrane solutions may include ultrafiltration, nanofiltration, microfiltration, reverse osmosis, forward osmosis, and electrodialysis, as discussed above with regard to filtration pretreatment. Other embodiments may include removing metals from water by chemical separation methods such as precipitation, coagulation, and/or flocculation. Various electrochemical treatments which may be used in some embodiments for removing metal species include electrochemical oxidation or reduction and electroflocculation. In addition, ion exchange treatments can be viewed as a form of electric-based separation and are an effective means to remove metal ions in some embodiments.

[0127] In some embodiments, cationic exchange may be used to eliminate or reduce the

concentration of one or more metal contaminants. For example, a cation exchange membrane may be deployed to simultaneously reduce the concentration of multiple cationic transition metal species (e.g.  $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Mn}^{3+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Cu}^{1+}$ ,  $\text{Pb}^{2+}$ ,  $\text{Cd}^{2+}$ ) that can scavenge solvated electrons. Cation exchange membranes can also reduce the concentration of or substantially eliminate alkaline metal cations such as  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  which may then be precipitated as  $\text{Mg}(\text{OH})_2$  and  $\text{Ca}(\text{OH})_2$ , respectively, upon addition of a base. Inclusion of a base may be used to achieve a high pH condition for the Advanced Reductive Process, as discussed further below. However, fine precipitates of  $\text{Mg}(\text{OH})_2$  and or  $\text{Ca}(\text{OH})_2$  result in light scattering, which may also reduce the number of photons that are available for absorption by the sensitizer. The consequence may be higher energy usage and/or longer reaction times. Therefore, pretreatment methods that facilitate the removal of  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  could be desirable.

[0128] Solids. Depending upon the source of the waste stream, some embodiments may include a step of settling the waste stream, which may be done prior to and/or after other pretreatments, such as prior to and/or after oxidation pretreatment. This optional settling step may be used to let solids such as soil particles settle out of the liquids and improve UV transmission. For example, pretreatment of waste streams including landfill leachate and natural water sources may include a settling step, which may include letting the waste stream sit for a period of time such as at least one hour, such as about one hour to one day, or about 6 hours to about 18 hours, or about 10 to about 14 hours, or about 12 hours. The amount of time needed for the settling step, if any, may depend upon the source of the waste stream and the level of solids present. Once complete, the liquid component may be removed from the settled solid component and then processed further by pretreatment and UV photoreduction to destroy the PFAS.

[0129] Oxidative pretreatment. In some embodiments, oxidative pre-treatment processes may be utilized for the treatment of PFAS including targeted fluorotelomer species. In some embodiments, the partial breakdown of long-chain telomers may be done by an oxidative process.

[0130] Oxidative pretreatment may be used, for example, for the treatment of fluorotelomer species contained in aqueous film forming foam (AFFF) products. Oxidative pre-treatments and other chemical treatments are also beneficial for PFAS in wastewater and concentrated sources of PFAS such as concentrates generated by a foam fractionation process. Foam fractionation occurs when a gas (for example, air or nitrogen) is bubbled through water that contains PFASs. The PFASs attach to the bubble and are brought to the surface where the foam can be captured. In some cases, an additional surfactant is added to facilitate the process.

[0131] The pretreatment can utilize one or more technologies that can be applied in combination, simultaneously and/or sequentially, according to some embodiments. For example, oxidative treatments may be utilized to reduce or eliminate multiple organic species like humic acid and/or fulvic acid. Humic acid and fulvic acid absorb in the UV spectrum and their presence may reduce the number of photons absorbed by the sensitizer. A cationic exchange media may be used to eliminate or reduce the concentration of one or more metal contaminants, as described above. Pretreatment methods may include the removal of  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  in various embodiments.

[0132] An example of a sequential pre-treatment would be to perform an oxidative pre-treatment, followed by flowing the solution through an ion exchange membrane, followed by a nanofiltration step. However, in some embodiments, such as when the purpose is to remove  $\text{Mg}^{2+}$  and/or  $\text{Ca}^{2+}$ , then the oxidative pre-treatment could be omitted. For example, an ion-exchange membrane could be used, and subsequent nanofiltration could be omitted. Alternatively, a base such as  $\text{NaOH/KOH}$  could be added to increase the pH to remove the  $\text{Mg}^{2+}$  and/or  $\text{Ca}^{2+}$  to cause precipitation, followed by separation such as through a sediment tank or other methods.

[0133] In some embodiments, the oxidative pretreatment processes disclosed herein may be utilized for the treatment of targeted fluorotelomer species, for example, those contained in

aqueous film forming foam (AFFF) products. The thermal and ozone oxidation pretreatment processes described herein may also be used to treat waste streams generated by foam fractionation processes. Foam fractionation occurs when a gas (for example, air or nitrogen) is bubbled through water that contains PFASs. The PFASs attach to the bubble and are brought to the surface where the foam can be captured. In some cases, the foam fraction may include an additional surfactant which was added to facilitate the process.

[0134] Depending upon the source of the waste stream, some embodiments may include a step of settling the waste stream prior to and/or after oxidation pretreatment, as discussed above.

[0135] In addition to solid particles which may be present in the waste stream, other substances present in the waste stream may also reduce UV transmission or the chemical process of photoreduction. It is, therefore, useful to pretreat the waste stream to improve UV transmission, but importantly not to introduce any substance that would interfere with the UV photoreduction process. Various embodiments disclosed herein for oxidative pretreatment can pretreat the waste stream to not only improve UV transmission but do so without disruption the UV photoreduction reaction. In some embodiments disclosed herein, such as embodiments for oxidative pretreatment, subsequent UV photoreduction may be improved even without improving UV transmission. For example, pre-treatment may not result in improvement in UV transmission but may still result in improved photolysis but other means, such as possibly by the pretreatment products interacting with the reagents used in photolysis.

[0136] Pretreatment methods which may be used in various embodiments include oxidation of the waste stream. For example, the waste stream may be pretreated using thermal oxidation. In other embodiments, it may be pretreated using ozone oxidation.

[0137] Embodiments which include thermal oxidation may include combining the waste stream with chemical additives and adjusting the pH. The chemical additives may include a persulfate and an acid or base to adjust the pH.

[0138] In some embodiments, the persulfate may be potassium persulfate, sodium persulfate, and/or aluminum persulfate, for example. The amount of persulfate used may be adjusted as needed to achieve the desired concentration in the final treated solution. For example, the concentration of persulfate may be about 100 to about 200 mM, or about 125 mM to about 175 mM, or about 140 to about 160 mM, or about 150 mM in the final solution.

[0139] In some embodiments, the base may be sodium hydroxide, potassium hydroxide, and/or calcium hydroxide, for example. In some embodiments, the acid may be sulfuric acid, hydrochloric acid and/or phosphoric acid, for example. The amount of acid or base may be adjusted, as needed, to achieve the desired pH. For example, when the thermal oxidation is performed under basic conditions, the pH may be adjusted to about 12, such as about 10 to about 14, or about 11.5 to about 12.5, or about 11.8 to about 12.3. When the thermal oxidation is performed under acidic conditions, the pH may be adjusted to about 3.0, such as about 1.5 to about 5, or about 2 to about 4 or about 2.5 to about 3.5, for example.

[0140] Thermal oxidation may be performed in a vessel in which the wastewater is treated at elevated temperature and pressure. Examples of vessels which may be used include autoclaves, for example. In some embodiments, the thermal oxidation process may be conducted in the same vessel as the UV treatment, such as in the sequential batch mode. In other embodiments, the oxidation process may be conducted in a separate treatment vessel prior to the UV photo treatment in the UV photo treatment vessel.

[0141] In some embodiments, the thermal oxidation pretreatment may be performed at an increased temperature. For example, the wastewater and added chemicals may be heated to a temperature of about 80 to about 160 degrees Celsius, or about 100 to about 140 degrees Celsius, or about 115 to about 125 degrees Celsius, or about 120 degrees Celsius, though other temperatures may also be used.

[0142] In some embodiments, thermal oxidation may be performed at an increased pressure along

with the increased temperature. For example, the wastewater and added chemicals may be heated at a pressure of about 0.5 to about 10 bar, or about 1 to about 5 bar, or about 1.5 to about 2.5 bar such as about 2 bar.

[0143] Embodiments which include ozone oxidation may include combining the waste stream with a base such as sodium hydroxide, potassium hydroxide, and/or calcium hydroxide. The amount of base used may be adjusted as required to raise the pH to the desired level, such as a pH about 10 to about 14, or about 11.5 to about 12.5, or about 11.8 to about 12.3, or about 12.

[0144] The wastewater including the base may then be treated by ozone oxidation. For example, the waste stream may be treated with an ozone generator, such as a portable ozone generator like the MultiPurpose Ozone Machine available from Shenzhen VANSU Technology Co., of China. The treatment may be at a rate of about 500 mg/h O<sub>3</sub> to about 2000 mg/h O<sub>3</sub>, such as 800 mg/h O<sub>3</sub> to about 1000 mg/h O<sub>3</sub>, or about 1000 mg/h O<sub>3</sub>, for example. The treatment duration may be about 3 to about 9 hours, such as about 7 to about 10 hours, or about 6 hours. The duration of treatment may depend upon the rate of ozone production and exposure.

[0145] Pretreatment with thermal oxidation or ozone oxidation and optionally a settling step may result in substantial improvement of UV transmission. For example, UV transmission may increase from 0% to about 10-20%, or to about 25-45%.

[0146] Furthermore, pretreatment with thermal oxidation or ozone oxidation and optionally a settling step may result in substantial improvement of UV transmission without the separation of the PFAS from the liquid. This is an improvement over some pretreatment methods, in which removal of substances which result in improvement of UV transmission also removes a portion of the PFAS. This splitting of the PFAS results in the requirement to treat two PFAS streams, substantially increasing the complexity and cost of treatment. In contrast, the oxidative pretreatment methods disclosed herein result in can improve the UV transmission to enhance PFAS destruction without removing PFAS from the wastewater and thereby maintaining a single waste stream for subsequent treatment.

[0147] Following pretreatment according to the embodiments described herein, the wastewater may be treated using UV photoreduction. However, in some cases, it may be preferable to dilute the waste stream prior to UV photoreduction. For example, the waste stream may be diluted between about 1.5 and about 10 times, such as about 2 to about 5 times, or about 2 to about 3 times. The amount of dilution may depend upon the source and nature of the waste stream. However, due to the improved UV transmission (without disruption of UV photoreduction) produced by various embodiments, less dilution is required. This results in a much more efficient process, because the treatment volume is not as substantially increased as compared to some other methods.

[0148] Following pretreatment, and optional dilution, the waste stream may be treated to destroy the PFAS, such as using a photoreactor to perform UV photoreduction. Various embodiments employ a photoreactor including a light source which delivers a narrow range of ultraviolet light radiation with a peak at approximately 222 nm, such as a krypton/chloride excimer lamp.

[0149] The photoreduction method is based on generating a highly reducing species, generally a solvated electron produced by the irradiation of a photosensitizer. Oxidative pretreatment of the wastewater as described herein allows increased the efficiency of the photochemical destruction of PFAS and allow photochemical methods to be more generally used on a variety of PFAS-containing waste streams.

[0150] In some embodiments, the UV photoreduction process may be performed using one or more reactor vessels with one or more UV light sources as described further below. The reactor is charged with pretreated wastewater including PFAS, water and sensitizers capable of absorbing UV light and producing a reactive species. In addition, there optionally can be one or more other chemical additives to promote the reaction.

[0151] FIG. 5 presents an example of a method of PFAS treatment that may be used in various embodiments. The method begins with optionally settling of the wastewater **10**, followed by

decanting or otherwise removing the liquid from the settled wastewater **20**. For example, as an alternative to decanting, the clarified water could be pumped off the top above the solids, the solids could be pumped or drained from the bottom beneath the clarified water, or other separation methods may be used. Next, the optionally decanted (or otherwise separated) wastewater is pretreated **30** such as by oxidative pretreatment. The pretreated wastewater is then optionally diluted **40**, and then the pretreated and optionally diluted wastewater is photoreduced **50** such as by UV treatment at 222 nm and/or 254 nm.

[0152] FIG. **6** presents a diagram of a method of thermal oxidation and photoreduction. The method begins with optionally settling of the wastewater **110**, followed by decanting or otherwise removing the liquid from the settled wastewater **120**. Next, the optionally decanted (or otherwise separated) liquid wastewater is mixed with persulfate and acid or base **130**. The wastewater is then pretreated by thermal oxidation **140** by subjecting it to increased temperature and pressure for a sufficient period of time to complete the reaction. Next, the pretreated wastewater may optionally be diluted **150**, and mixed with the photosensitizer **160**. The order of steps **150** and **160** may alternatively be reversed or performed simultaneously. The wastewater is then subjected to photoreduction **170** such as by UV treatment at 222 nm and/or 254 nm.

[0153] FIG. **7** presents a diagram of a method of ozone oxidation and photoreduction. The method begins with optionally settling of the wastewater **210**, followed by decanting or otherwise removing the liquid from the settled wastewater **220**. Next, the optionally decanted liquid wastewater is mixed with base **230**. The wastewater is optionally settled **240**, then subjected to ozone oxidation **250** for a sufficient period of time to complete the pretreatment reaction. Next, the pretreated wastewater may optionally be diluted **260**, and mixed with the photosensitizer **270**. The order of steps **260** and **270** may alternatively be reversed or performed simultaneously. The wastewater is then subjected to photoreduction **280** such as by UV treatment at 222 nm and/or 254 nm.

[0154] The methods shown in FIGS. 5-7 may optionally include additional settling and/or decanting steps (or other separation steps), or the settling and/or decanting steps (or other separation steps) may be performed at other times. For example, the method of FIG. **6** may include an optional settling and decanting step (or other separation step) after mixing the wastewater with the persulfate and the acid or base **130**, followed by decanting (or otherwise removing) the separated liquid, then applying thermal oxidation **140** to the decanted liquid. As another example, the method of FIG. **7** may include a decanting step (or other form of removal of the separated liquid) after the step of settling the wastewater **240** and before the step of applying ozone oxidation **250**.

[0155] In an exemplary embodiment, a wastewater stream including PFAS is settled for an appropriate period of time to allow settling of the solids, such as about 6 to about 18 hours. The liquid is decanted or otherwise separated from the solid and is combined with a persulfate and an acid or base. The resulting wastewater includes the persulfate at a concentration of about 150 mM and a pH of about 11 to about 13 or about 12. The wastewater is then treated at an elevated temperature, such as about 100 to about 140 degrees Celsius or about 100 degrees Celsius and about 0.5 to about 10 bar, or about 1 to about 5 bar, or about 1.5 to about 2.5 bar such as about 2 bar, for a sufficient period of time to complete the reaction, such as about 1 to about 3 hours, or about 2 hours. Following pretreatment, the wastewater is then combined with a photosensitizer including a sulfite and a halide salt, and a base. The resulting wastewater includes about 40 to about 60 mM sulfite, about 7 to about 13 mM halide salt, and a pH of about 13 to about 15. Alternatively, the resulting wastewater may include about 5 to about 15 mM sulfite, about 1 to about 4 mM halide salt, and a pH of about 12. The wastewater may then optionally be diluted about 2 to 5 times, or about 2 to 3 times. The wastewater is then treated by UV photoreduction at 222 nm and/or 254 nm for the necessary period of time to complete the reactions, such as about 1 h to about 24 h, or about 2 h to about 12 h or about 4 h to about 8 h. After completion of photoreduction, the

majority of the PFAS may be destroyed, such as about 70% to about 90%, or about 80%. For example, after about 8 hours of photoreduction, about 80% of the PFAS may be destroyed as compared to the original level of PFAS in the wastewater.

[0156] In some embodiments, additional pretreatments may also be employed, in addition to those disclosed above. For example, pre-treatment to remove nitrate, nitrite or other contaminants can be accomplished by several methods including chemical reduction, ion exchange membranes, electrodialysis, electrochemical reduction, photochemical reduction, and bioremediation wherein contaminants are degraded by an organism. In addition, for removal of UV inhibiting substances, for example, techniques such as flocculation, coagulation, clarification, filtration, centrifugation, and sedimentation may be used. For the removal of organic constituents, for example, treatments such as chemical oxidation, such as photochemical, or electrochemical oxidation processes may be utilized, as well as other chemical or ozonolysis methods. In addition, biological or hydrothermal treatments may be utilized. Other oxidative species that may be used include permanganate species. The oxidative pre-treatment systems and methods described herein may be used in combination with any of these processes.

[0157] A system for the UV destruction of PFAS can consist of a single reactor vessel where the oxidative pretreatment, optional additional pretreatments such as settling, UV photoreduction, and other steps are sequentially performed. Alternatively, such as to maximize the efficiency of the process, the above processes may occur in a single vessel or separate vessels or chambers.

#### Photolysis Step(s)

[0158] UV Reactors. In some embodiments, the system for the UV destruction of PFAS may include a single reactor vessel in which pretreatment, photolysis, and the post-treatment steps are sequentially performed. In other embodiments, one or more or all of the steps of pre-treatment, photolysis, and post treatment may occur in separate vessels or chambers of a vessel, such as for continuous processes.

[0159] In some embodiments, the UV photoreduction process may be performed using one or more reactor vessels with one or more UV light sources. The reactor is charged with pretreated wastewater including PFAS, water and sensitizers capable of absorbing UV light and producing a reactive species. In addition, there optionally can be one or more other chemical additives to promote the reaction.

[0160] The reactor vessel may include one or more UV light sources emitting light, such as UV light at 222 nm or UV lights at 254 nm. In some embodiments, multiple wavelengths may be emitted from a light source, or from various light sources, and other wavelengths of lights in addition to 222 nm and 254 nm may contribute to PFAS photoreduction, such as 185 nm.

[0161] The photoreactor may be used alone, or in combination with other reactors, such as in a serial configuration, which may also employ a photoreduction at the same or different wavelength or may employ other PFAS destruction methodologies. Alternatively, one or more steps may be performed in the same vessel.

[0162] Examples of PFAS capture systems, treatment systems, and pretreatment are provided in the applicant's other applications, such as U.S. patent application Ser. No. 18/212,603, entitled METHOD AND APPARATUS FOR THE DESTRUCTION AND DEFLUORINATION OF PER- AND POLYFLUOROALKYL SUBSTANCES (PFAS), FLUOROTELOMERS AND OTHER PERSISTENT ORGANIC POLLUTANTS filed Jun. 21, 2023, U.S. Pat. App. No. 63/513,782 entitled PROCESSES FOR EFFICIENT PHOTOCHEMICAL DESTRUCTION OF PFAS FROM WASTE STREAMS filed Jul. 14, 2023, and U.S. patent application Ser. No. 18/555,135 entitled SORBENTS AND METHODS FOR THE CAPTURE AND DEFLUORINATION OF PER AND POLY FLUOROALKYL SUBSTANCES (PFAS) and filed Oct. 12, 2023 (national stage entry), the disclosures of all of which are hereby incorporated by reference. The systems and methods described herein may be used in combination with the methods and systems described in these applications.

[0163] One example of a photoreactor which may be used in various embodiments comprises a one or more lamps, such as lamps including cylindrical bulbs or other bulb shapes, and one or more photoreactor vessels configured such that the light of the lamp will project onto the contents of the reactor vessel or vessels. The lamps may be supported on a frame such as a metal support frame, at a desired distance over a top surface of a photoreactor vessel and/or above the top surface of liquid in the photoreactor vessel when in use to shine directly on the surface of the reaction solution or to shine through the reactor vessel wall. Alternatively, the lamp may fit into the reactor vessel to shine light directly onto the contents from within the reactor vessel. The bulb may be protected and/or separated from the reaction solution within the reactor vessel, such as by a sleeve or other barrier. In some embodiments, the photoreactor vessel may include two cylindrical lamps and a support frame holding the two lamps horizontally at a selected distance above a level surface of a photoreactor vessel. Other light and reactor vessel configurations and orientations may be used to optimize energy delivery and PFAS destruction.

[0164] The photoreactor vessel may be any appropriate material such as quartz or other material which is non-reactive and is transparent to 222 nm radiation. In other embodiments, such as those in which the bulb is located within the reactor vessel, the reactor vessel need not be transparent and may be a nontransparent and nonreactive material such as stainless steel. The vessel may be configured to contain a fluid and may include a top which may seal the vessel. In some embodiments, the photoreactor may include a single reactor vessel, while in others it may include more than one reactor vessel, such as two or three reactor vessels or more. The reactor vessel may be any size or shape. In some embodiments, the reactor vessel is cylindrical.

[0165] The lamp(s), lamp support, and the reactor vessel may be contained in a housing such as a metal enclosure or other enclosure.

[0166] Examples of lamps which may be used in various embodiments include krypton/chloride excimer lamps emitting radiation at 222 nm. Other excimer lamps which emit a narrow band of radiation at other wavelengths could alternatively be used. The lamps may consume 100 Watts of power or could consume more or less power. The power supply to the lamps may be 20 kilovolts or may be more or less than 20 kilovolts. In some embodiments, the lamp powers for lamps including those emitting at 222 nm and 254 nm, for example, may be between about 50 and about 5000 W, such as between about 100 and about 1000 W or between about 100 and about 300 W. Single lamps may be used or multiple lamps, which may be identical or different.

[0167] The photoreaction methods as described herein may be performed at room temperature or at a temperature greater than room temperature. For example, in some embodiments, the temperature of the photoreactor may be between about 55 and about 60 degrees Celsius during the reaction. However, higher or lower temperatures could alternatively be used. In addition, heating and/or cooling elements could be added to the reactor and/or to the room containing the reactor to raise or lower the temperature, such as air-ducting, fans and lamps.

[0168] The reactor solution may be stationary during UV treatment, or it may be agitated. For example, the reactor may include stirrers or agitators with the capacity to stir or agitate the solutions. In some embodiments, stirring or agitating the reactor solution during irradiation may facilitate exposure of PFAS compounds to regions of higher radiation. Alternatively, the solution could be recirculated through a heat exchange unit.

[0169] Ultimately, optimization of reactor solution for efficiency may also depend upon direct agitation or stirring of the compound to expose more solution constituents to a region of higher radiation field in a smaller amount of time.

[0170] In some embodiments, the PFAS irradiation at 222 nm and/or 254 nm may be performed in a reaction solution including only an aqueous solution of the PFAS. However, the results may be improved by including appropriate reducing solutions at appropriate concentrations. This may result in faster, more efficient, and more complete destruction of PFAS.

[0171] Photoreduction of the PFAS may destroy the PFAS through mineralization of the PFASs,

including converting the carbon-fluoride bond to the fluoride ion and carbon species, such as acetate, carbon dioxide and/or carbonate. In this context mineralization may include reduction of the carbon-bound fluorine on PFAS to the fluoride ion  $F^-$ .

[0172] Some embodiments result in complete destruction of the PFAS or near complete destruction, such as greater than 99% destruction. Some embodiments result in at least 90% or at least 95% destruction of PFAS, such as about 90% to about 100%, or about 95% to about 100% destruction of PFAS.

[0173] The duration of treatment necessary to achieve complete destruction of the PFAS or near complete destruction may depend upon the design of the photoreactor which is used, as well as other variables.

[0174] Various embodiments include UV reactors for photochemical destruction of PFAS. In some embodiments, the UV reactor includes a photochemical chamber containing one or more UV light sources. The UV reactor may further include a recirculating system which may be equipped with a heat-exchange system configured to control the solution temperature. The UV reactor may further include a sensor module configured to allow continuous monitoring of the physical and/or chemical state of the reaction solution. In some embodiments, the UV reactor may also include one or more ports for adding additional reagents and/or sampling the reaction mixture.

[0175] One example of a UV reactor according to various embodiments includes a reactor providing greater than 1000 Ws of UV light and configured to maintain the solution at less than 50° C. The UV reactor includes a sensor module that may be configured to provide information to help maintain optimal photochemical conditions through a closed-looped control system to automatically maintain the conditions. The sensor system in some embodiments one or more sensors configured to monitor one or more of the following: temperature, pressure, pH, UV intensity, fluoride ion concentration, and oxidation-reduction potential.

[0176] The additives charged from the ports can be added either continuously or in one or more batches. Typical additives include, but are not limited to, sulfite salts, initiators, bases such as sodium hydroxide or sodium carbonate.

[0177] Depending on the waste streams, it may be useful to perform both an oxidative treatment and a reductive treatment. Although these two treatments could be performed sequentially in the same vessel, they could also be performed in separate vessels. The sequence that these steps are performed in could vary depending on the components in the waste stream.

[0178] An example of a UV reactor as the photochemical portion of a treatment system is shown in Figure A. The UV reactor in FIG. 8 can be run in a batch or a continuous mode. One embodiment of this design would be a continuous stirred tank reactor.

[0179] Sensitizers. Various embodiments include a sensitizer which is added to the wastewater. The photoreduction method is based on generating a highly reducing species, such as a solvated electron, produced by the irradiation of a photosensitizer.

[0180] In the UV-ARP, the sensitizer absorbs the UV photon and as a result an oxidized sensitizer and a solvated electron are generated as shown below:

Sensitizer +  $h\nu$  (UV photon)  $\rightarrow$  Sensitizer<sup>sup.+</sup> + e<sup>sub.aq.sup.-</sup> (Solvated electron)      a.

[0181] Photosensitizers which may be used in various embodiments include halides, pseudo halogens, inorganic oxoanions, anionic metal complexes, metal clusters, Zintl Compounds, nanometal particles of a transition metals, organic anions, nitrogen heterocycles, boron-doped nanodiamonds, and/or nitrotriacetic acid. These sensitizers may be used in combination or separately in conjunction with different light sources.

[0182] Examples of halides which may be used include iodide, chloride, and bromide, Examples of pseudohalogens which may be used include cyanide, isocyanate, cyanate, isocyanide, isocyanate, azide, hydroxide, hydrosulfide, hydroselenide, hydrotelluride, fulminate, thiocyanate,

selenocyanate, tellurocyanate, isothiocyanate, nitroxide, tetracarbonyl cobaltate, trinitromethanide, tricyanomethanide, 1,2,3,4-thiatriazol-5-thiolate, fulminate, cyaphide, and auride. Examples of inorganic oxoanions which may be used include sulfite ( $\text{SO}_3^{2-}$ ), sulfate ( $\text{SO}_4^{2-}$ ), hyposulfite ( $\text{SO}_2^{2-}$ ) thiosulfate ( $\text{S}_2\text{O}_3^{2-}$ ), carbonate ( $\text{CO}_3^{2-}$ ), phosphate ( $\text{PO}_4^{3-}$ ), phosphite ( $\text{PO}_3^{3-}$ ), hypophosphite ( $\text{PO}_2^{3-}$ ), and borate ( $\text{BO}_3^{3-}$ ), including protonated forms of these anions (e.g.  $\text{HSO}_3^-$ ,  $\text{HSO}_4^-$ ,  $\text{HCO}_3^-$ ). Examples of anionic metal complexes which may be used include ferricyanide ion, ferrioxalate ion, tetrachloroplatinate ion, hexachloroiridate ion, cyanocuprates and cerium(III) complexes). Examples of metal clusters that may be used include  $\text{Mo}_6\text{Cl}_{14}^{2-}$ ,  $\text{Zr}_6\text{Cl}_{12}$ ,  $\text{Ta}_6\text{Cl}_{18}^{4-}$ ,  $\text{Re}_3\text{Cl}_{12}^{3-}$ , and iron sulfur clusters. Examples of Zintl Compounds that may be used include  $[\text{Bi}_3]^{3-}$ ,  $[\text{Sn}_9]^{4-}$ . Examples of nanometal particles of a transition metals that may be used include gold, copper and iron. Examples of organic anions that may be used include ascorbic acid anion, ascorbic acid dianion, phenolates, cresolates, dihydroxybenzenes anions, methoxyphenolates, thiophenolates. Examples of nitrogen heterocycles that may be used include indole-3-acetic acid.

[0183] Other components which may be included in the reactor include photosensitizers such as halide salts alone or in combination with other components such as sulfites. The concentration of the sensitizer will depend on the electronic absorption of spectra of the sensitizer, the spectral output of the lamp, and the concentration of other sensitizers contained within the reactor. The concentration of halide salt may be about 1 mM to about 150 mM, or about 5 to about 15 mM, or about 7 mM to about 13 mM. For example, the concentration of KI may be about 1 mM to about 10 mM when UV 254 nm or UV 222 nm radiation is utilized in the photoreactor. The concentration of KBr may be about 10 mM to about 150 mM when UV 22 nm radiation is utilized, for example. The concentration of sulfite may be about 5 mM to about 100 mM, such as about 25 mM to about 75 mM, or about 35 mM to about 65 mM, or about 45 mM to about 55 mM. For example, when UV 222 nm light is used in the reactor, the concentration of sulfite may be about 5 mM. The pH may be greater than 10, or greater than 12, or greater than 13, for example. In some embodiments, the pH may be about 11 to about 15, or about 13 to about 15, for example. In other embodiments in which UV 185 nm light is utilized in the photoreactor, the concentration of photosensitizers, which may include halide salts, sulfites and sulfates may be about 1 micromolar to about 10 mM. For example, the concentration of NaCl may be around 150 micromolar, and the concentration of sulfate and sulfite 1 mM. The pH range of the solution may be greater than about 7, or greater than about 8, or greater than about 10, for example.

[0184] Other components which may be included in the reactor include halide salts alone or in combination with other components such as sulfites. In some embodiments, such as embodiments utilizing UV 222 nm or UV 254 nm light, KI and  $\text{Na}_2\text{SO}_3$ , may be included in the reactor solution, such as 1 mM KI and 5 mM  $\text{Na}_2\text{SO}_3$ , though higher or lower concentrations may be used, such as 10 mM KI and 50 mM  $\text{Na}_2\text{SO}_3$ . Other components which may alternatively be used in the reactor solution include KBr and  $\text{Na}_2\text{SO}_3$  such as approximately 10 mM KBr and 50 mM  $\text{Na}_2\text{SO}_3$  when UV 222 nm light is utilized, or approximately 150 mM KBr and 5 mM  $\text{Na}_2\text{SO}_3$  when UV 222 nm light is utilized, though higher or lower concentrations may alternatively be used. In some embodiments utilizing either UV 222 nm or UV 254 nm light, the photosensitizer includes about 10 mM  $\text{Na}_2\text{SO}_3$  and about 2 mM KI at a pH of about 12. In some embodiments, the photosensitizer includes about 50 mM  $\text{Na}_2\text{SO}_3$  and about 10 mM KI at a pH of about 14. Still other embodiments may include only a sulfite such as  $\text{Na}_2\text{SO}_3$ , such as approximately 50 mM  $\text{Na}_2\text{SO}_3$ , though higher or lower concentrations may alternatively be used.

[0185] In some embodiments, a lower concentration of the additional components may be used, such as micromolar concentrations, for components such as a halide salt. These low levels may

optimize and facility efficient light absorption at 222 nm and 185 nm. For example, micromolar concentrations of halide salt may be used.

[0186] In some embodiments, it is preferable to maintain a high pH during photoreduction, such as a pH of 10 or more, or 11 or more, or 12 or more, or 13 or more. Therefore, in addition to the reagents discussed above, it may be useful to include a base such as sodium carbonate and/or one or more other bases such as hydroxide to increase the efficiency of the reaction.

[0187] In some embodiments, iodide (I.sup.-) may be used as the photosensitizer during photoreduction. As a result of its absorption of a UV photon, a variety of iodine-containing species are potentially generated including but not limited to the following: Iodine radical (I.sup.-), Iodine (I.sub.2), Iodine radical anion (I.sub.2.sup.-.Math.) and triiodide anion (I.sub.3.sup.-). Many of these iodine-containing species also react with solvated electrons. If these species are not removed from the system, the concentration of one or more of these species increases and the resultant efficiency of PFAS destruction is reduced.

[0188] In addition, in some cases the water to be treated contains other materials that can interfere with the efficiency of the reaction. Also, the pH plays an important role in the reaction efficiency. In some embodiments, the pH may be above 9 or about 10 such as between 12-14. Furthermore, higher pH may increase the extent of PFAS mineralization through its influence on chemical degradation mechanisms. In some cases, chemicals may be added to modify the properties of the liquid to be treated which could results in great cost and generation of greater amounts of waste.

[0189] Photosensitizers, including but not limited to those aforementioned, may be further synthetically modified to induce PFAS selectivity in order to improve the kinetics and extent of PFAS mineralization in the photochemical reaction. Means of imbuing PFAS selectivity according to various embodiments may include but need not be limited to the addition of moieties or functional groups which are fluorophilic, hydrophobic, or those which induce electrostatic interactions with the charged terminal groups of the PFAS molecules. PFAS-selective synthetic modifications of the photosensitizer may encompass one or more of these moieties simultaneously. These modified PFAS-selective photosensitizers may further be intercalated into mesoporous clay materials including but not limited to montmorillonite, bentonite, or kaolinite. PFAS sequestration into the mesoporous clay's interlayer will thus co-localize the PFAS molecule with the photosensitive active site, in a local environment with an absence of scavengers and co-contaminants.

[0190] The effectiveness of these respective sensitizers, and their selection for a particular embodiment, may be dependent on the wavelength of the light source.

[0191] Light sources. Low pressure mercury lamps, medium pressure mercury lamps and mercury amalgam lamps may be used as the source of UV radiation in various embodiments because of their relatively low cost and high efficiency of converting electrical energy into UV photons. Mercury vapor lamps exhibit pronounced spectral lines in the ultraviolet and visible. For PFAS destruction, 184.5 nm (typically referred to as 185 nm) and 253.7 nm (typically referred to as 254 nm) are important wavelengths. However, other light sources can also be used in various embodiments. In particular, various excimer lamps which have high efficiency, high-powered, narrow-band radiation across the UV spectrum (near UV to Vacuum UV) are also excellent light sources and may be used in various embodiments. Excimer lamps are a type of discharge lamp that involves rare gases such as argon (Ar), krypton (Kr) or Xenon (Xe), or halogen dimers (F.sub.2, Cl.sub.2 Br.sub.2 or I.sub.2) or combinations of halogens and rare gases. The UV light from an excimer source is due to emission from the excited state of rare gas dimer (Ar.sub.2\*, Kr.sub.2\* and Xe.sub.2\*), halogen dimers (F.sub.2\*, Cl.sub.2\* Br.sub.2\* or I.sub.2\*) and rare-gas halide excimers (ArF\*, ArCl\*, ArBr\*, ArI\*, KrF\*, KrCl\*, KrBr\*, KrI\*, XeF\*, XeCl\*, XeBr\* and XeI\*), where the asterisk denotes an excited state. Examples of excimers light sources and their principle emission output that may be used in various embodiments include XeXe\* (172 nm), ArCl\* (175 nm), KrI\* (190 nm), ArF\* (193 nm), KrBr\* (207 nm), KrCl\* (222 nm), KrF\* (248 nm), XeI (253

nm), Cl.sub.2\* (259 nm), XeBr\*, Br.sub.2\* (289 nm) and XeCl\* (308 nm). The preferred lamps have outputs between 190 nm and 289 nm. The wavelength output and availability of powerful KrCl\* excimer lamps make them especially preferred in certain embodiments. Although the efficiencies of excimer lamps may not be as high as the efficiencies from mercury lamps, the ability to fine tune the light emission to a given sensitizer is useful to the overall effectiveness of photochemical process in various embodiments. These lamps have the added advantage of not containing mercury.

[0192] Other UV light sources that may be used in various embodiments include xenon arc lamps, deuterium arc lamps mercury/xenon arc lamps, metal/halide arc lamps, and UV LEDs. The amount of light (power) from a UV LED is generally much lower than mercury or other discharge lamps and therefore multiple LEDs may be included in various embodiments to destroy PFASs in a time frame of minutes to hours, for example.

[0193] The light sources included in various embodiments produce sufficient energy to generate a solvated electron from the sensitizer. The UV light produced by the light sources and used in various embodiments may have a wavelength of between about 190 nm and about 300 nm. For example, some embodiments may include mercury lamps with a strong output peak at 254 nm. In other embodiments, higher energy (lower wavelength) irradiation may be used, such as excimer bulbs, for example, krypton/chloride excimer lamps. Ultraviolet Light emitting diodes can also be used as light sources.

[0194] Light sources, including but not limited to those listed above, may be used separately or in combination, either sequentially or simultaneously, in a single reactor or reactors in series.

[0195] Photolysis at 222 nm. Various embodiments described herein relate to systems and methods for the photochemical destruction of PFASs using 222 nm radiation using UV-ARP to generate a highly reducing species, such as a solvated electron, produced by the irradiation of a photosensitizer. The process and systems increase the efficiency of the photochemical destruction of PFAS, allow photochemical methods to be more generally used on a variety of PFAS-containing waste streams, and decrease the time required for PFAS destruction as well as the expense.

[0196] In various embodiments, the photochemical system includes a reactor vessel with one or more UV light sources emitting light at 222 nm. The reactor is charged with a liquid consisting of a PFAS, water (and/or another solvent), and sensitizers capable of absorbing UV light and producing a reactive species. In addition, there optionally may be one or more other chemical additives to promote the reaction. The photoreactor may be used alone, or in combination with other reactors, such as in a serial configuration. These other reactors may also employ an UV-ARP at the same or different wavelengths or may employ other PFAS destruction methodologies. In addition, the photoreactor system may include one or more processes for pretreatment of the PFAS contaminated material, such as wastewater or other water sources, as well as posttreatment and polishing processes.

[0197] Various embodiments employ a photoreactor including a light source which delivers a narrow range of ultraviolet light radiation with a peak at approximately 222 nm, such as a krypton/chloride excimer lamp.

[0198] The photoreactor vessel may be any appropriate material such as quartz or other material which is non-reactive and is transparent to 222 nm radiation. (When UV-ARP is performed using light at different wavelengths, the photoreactor vessel should alternatively or additionally be transparent to that wavelength of radiation.) In other embodiments, such as those in which the bulb is located within the reactor vessel, the reactor vessel need not be transparent and may be a nontransparent and nonreactive material such as stainless steel. The vessel may be configured to contain a fluid and may include a top which may seal the vessel. In some embodiments, the photoreactor may include a single reactor vessel, while in others it may include more than one reactor vessel, such as two or three reactor vessels or more. The reactor vessel may be any size or shape. In some embodiments, the reactor vessel is cylindrical. The lamp(s), lamp support, and the

reactor vessel may be contained in a housing such as a metal enclosure or other enclosure. The same designs may be used for UV-ARP systems delivering at other wavelengths as well.

[0199] Examples of lamps which may be used in various embodiments include krypton/chloride excimer lamps emitting radiation at 222 nm. Other excimer lamps which emit a narrow band of radiation at other wavelengths could alternatively be used. The lamps may consume 100 Watts of power or could consume more or less power. The Excimer lamps systems, which may include the bulbs, wiring and ballasts (power supply), may have an overall power conversion efficiency of 0.1% to around 20%, with conversion efficiency declining as lamp intensity increases. The power supplied to the lamps may be around 20 kilovolts in some embodiments that support high power lamps, or may be around 3 kV for embodiments that support lamps of lesser intensity, for example.

[0200] The photoreaction methods as described herein may be performed at room temperature or at a temperature greater than room temperature. For example, in some embodiments, the temperature of the photoreactor may be between about 55 and about 60 degrees Celsius during the reaction. However, higher or lower temperatures could alternatively be used. In addition, heating and/or cooling elements could be added to the reactor and/or to the room containing the reactor to raise or lower the temperature, such as air-ducting, fans and lamps.

[0201] The reactor solution may be stationary during UV treatment, or it may be agitated. For example, the reactor may include stirrers or agitators with the capacity to stir or agitate the solutions. In some embodiments, stirring or agitating the reactor solution during irradiation may facilitate exposure of PFAS compounds to regions of higher radiation. Alternatively, the solution could be recirculated through a heat exchange unit.

[0202] Ultimately, optimization of reactor solution for efficiently may also depend upon direct agitation or stirring of the compound to expose more solution constituents to a region of higher radiation field in a smaller amount of time.

[0203] In some embodiments, the PFAS irradiation at 222 nm may be performed in a reaction solution including only an aqueous solution of the PFAS. However, the results may be improved by including appropriate reducing solutions at appropriate concentrations. This may result in faster, more efficient, and more complete destruction of PFAS.

[0204] Some embodiments result in complete destruction of the PFAS or near complete destruction, such as greater than 99% destruction. Some embodiments result in at least 90% or at least 95% destruction of PFAS, such as about 90% to about 100%, or about 95% to about 100% destruction of PFAS.

[0205] The duration of treatment necessary to achieve complete destruction of the PFAS or near complete destruction may depend upon the design of the photoreactor which is used, as well as other variables. However, in some embodiments, complete destruction may be achieved after about 5 minutes to about 6 hours of treatment, such as about 2 hours to about 5 hours of treatment to achieve complete or near complete (such as 99% or more) destruction of PFAS.

[0206] In some of the examples included herein, control samples were tested which did not include reagents. Even in the absence of reagents, irradiation at 222 nm results in the destruction of the PFAS through a process of direct photolysis. However, the PFAS destruction was much slower and less complete. In contrast, when the reagents were included, PFAS destruction was faster and more complete. It is believed that using the advanced reductive process described herein produced superior results through the production of solvated electrons which are capable of reacting with the carbon-fluorine bond rather than relying on the direct absorption of the energy by the PFAS and subsequent scission of bonds.

[0207] In addition, while direct irradiation at 222 nm in the absence of reagents may produce some enhanced photolysis of perfluoroalkylcarboxylic acids (PFCAs), fluorotelomers, unsaturated carboxylic acids, and GenX PFAS compounds as compared to photolysis at 254 nm, the 222 nm treatment alone has minimal performance/effectiveness against perfluoroalkylsulfonic acids. In contrast, the use of the advanced reductive process at 222 nm described herein results in more

rapid, more complete, and overall more efficient destruction of both perfluoroalkylcarboxylic acids (PFCAs) and perfluoroalkylsulfonic acids (PFSAAs).

[0208] Combination Photochemistry/Electrochemistry. In some embodiments, UV photolysis may be used in conjunction with an electrochemical system. This may be used, alone or in combination with other methods of UV photolysis described herein, and the combination can further enhance the destruction rate of PFASs. An example of an electrolytic cell which may be used in combination with photochemistry is the photo-electrolytic cell shown in FIG. 9, in which the cathode is immersed in an electrolytic solution with the UV lamp. This photo-electrolytic cell is like the photo-electrolytic cell discussed above with regard to FIG. 2. For example, the photo-electrolytic cell like the one shown may be used to reduce the photo-oxidized sensitizer back to the sensitizer to prevent the buildup of species that can react with solvated electrons. In other embodiments, the photo-electrolytic cell may be used to increase the pH around the electrode and therefore minimize the reactions of solvate electrons with protons. In still other embodiments, the photo-electrolytic cell may be used to produce hydrogen gas which, under some conditions, can increase the concentration of solvated electrons which can significantly increase the efficiency of photo-destruction of PFAS.

[0209] Consider that the oxidized sensitizer can undergo further reactions. For example, when iodide is the sensitizer, the following reactions can occur:

$I_{aq}^{sup.-} + h\nu \text{ (UV photon)} \rightarrow I_{aq}^{radical} + e_{aq}^{sup.-} \text{ (Solvated electron)}$

$I_{aq}^{radical} + I_{aq}^{sup.-} \rightarrow I_2^{sub.2}$  (iodine)

$I_2^{sub.2} + I_{aq}^{sup.-} \rightarrow I_3^{sub.3, sup.-}$  (triiodide anion)

[0210] The iodine radical, iodine, and the triiodide anion are all photolysis byproducts. All of these species are efficient scavengers of solvated electrons and have higher second order rates for the reaction with solvated electrons than PFASs. The presence and accumulation of these species reduces the efficiency of the destruction of PFASs and therefore various embodiments may remove these species. As discussed above, one way to accomplish this is to introduce a sacrificial reductant that is capable of reducing the photochemical byproducts back to the original sensitizer. An example of a sacrificial reductant which may be used in various embodiments is sulfite. Sulfite may react with the iodide products as follows:

$SO_3^{sub.3, sup.2-} + I_{aq}^{sup.-} \rightarrow SO_3^{sub.3} + I_{aq}^{sup.-}$

$2SO_3^{sub.3, sup.2-} + I_2^{sub.2} \rightarrow 2SO_3^{sub.3, sup.-} + 2I_{aq}^{sup.-}$

$2SO_3^{sub.3, sup.2-} + I_3^{sub.3, sup.-} \rightarrow 2SO_3^{sub.3, sup.-} + 3I_{aq}^{sup.-}$

[0211] These reactions are thought to occur through a series of sulfur-iodine intermediates. Moreover, the chemistry seems to be particularly well tuned for iodide.

[0212] In other embodiments, the iodide byproducts may be electrically reduced. For example, an electrochemical system may be used to regenerate the original sensitizer (iodide) from photolysis byproducts (iodine radical, iodine, and triiodide) in situ in the photolysis reactor. In the case of iodide as a sensitizer, the following reactions may occur at the cathode:

$I_{aq}^{sup.-} + e_{aq}^{sup.-} \rightarrow I_{aq}^{sup.-} \quad E^\circ = +0.93V/SHE$

$I_2^{sub.2} + 2e_{aq}^{sup.-} \rightarrow 2I_{aq}^{sup.-} \quad E^\circ = +0.620 V/SHE$

$I_{3(aq)}^- + 2e^- \rightarrow 3I_{(aq)}^-$   $E^\circ = +0.536 \text{ V/SHE}$

[0213] Depending on the pH and temperature of water, iodine can also be hydrolyzed and generate several products such  $I_{(aq)}^-$ ,  $IO_{(aq)}^-$ ,  $HOI_{(aq)}$  and  $HOI_{(aq)}$ . Electrodes which may be used in various embodiments may include Ru- or Pt-based electrodes and metal oxides such as  $TiO_2$  as a cathode material that can reduce triiodide into iodide, and graphene oxide deposited with Cu—Pt bimetallic nanoparticles to reduce triiodide to iodide.

[0214] In order to complete the circuit, a suitable oxidation process occurs at the anode. There are several possible anode reactions in aqueous medium, but the following reaction on the anode may occur when high overpotential is present:

$2H_2O \rightarrow O_2 + 4H^+ + 4e^-$   $E^\circ = -1.23 \text{ V/SHE}$

[0215] Combining the half-cell reactions of the reduction of iodine and the oxidation of water results in the following overall reaction in various embodiments:

$I_2 + H_2O \rightarrow 2HI + \frac{1}{2}O_2(g) + 2H^+$

[0216] The products from this reaction are acid and  $O_2$ , both of which are not desirable because they may react with solvated electrons. This problem can be ameliorated in various embodiments by addition of a base like sodium hydroxide to neutralize the acid or by removing the oxygen gas by sparging with an inert gas, for example. Another method to avoid oxygen interference is to have the electrodes in separate compartments.

[0217] In some embodiments, the production of  $O_2$  from  $H_2O$  oxidation may be avoided by including a sacrificial carbon layer of the electrode material or using porous carbon-based anode, for example. Oxidation of carbon at the anode is a faradaic process with the following reaction:

$\frac{1}{4}C + \frac{1}{2}H_2O \rightarrow \frac{1}{4}CO_2 + H^+ + e^-$   $E^\circ = 0.7-0.9 \text{ V/SHE}$

[0218] Oxidation of  $H_2O$  can be avoided by addition of a sacrificial reductant in various embodiments. As in the chemistry above for the UV Sulfite/ $I_2$ , sulfite could be added to the reaction solution. In this case, the anode and overall reaction would be the following:

Anode (oxidation):  $SO_3^{2-} + 2OH^- \rightarrow SO_4^{2-} + H_2O + 2e^-$   $E^\circ = 0.936 \text{ V/SHE}$

Cathode (reduction):  $I_2 + 2e^- \rightarrow 2I^-$   $E^\circ = +0.620 \text{ V/SHE}$

Overall reaction:  $I_2 + SO_3^{2-} + 2OH^- \rightarrow 2I^- + SO_4^{2-} + H_2O$

[0219] In this case, the sulfate ion ( $SO_4^{2-}$ ) is a reaction product as well as acid. Sulfate has a low affinity for solvated electrons and therefore would not compete with PFASs for solvated electrons.

[0220] Another option which may be used in various embodiments is to include in the reaction solution a polysulfide species like  $S_2^{2-}$  which undergoes oxidation:

Anode (oxidation):  $2S_2^{2-} \rightarrow S_4^{2-} + 2e^-$   $E^\circ = 0.497 \text{ V/SHE}$

Cathode (reduction):  $I_2 + 2e^- \rightarrow 2I^-$   $E^\circ = +0.620 \text{ V/SHE}$

Overall reaction:  $I_2 + 2S_2^{2-} \rightarrow 2I^- + S_4^{2-}$

[0221] Various embodiments may include electrochemistry to reduce other photosensitizers that have generated a solvated electron, and therefore been oxidized, back to the original

photosensitizer. For example, in some embodiments, irradiation of ferrocyanide  $\text{Fe(CN)}_6^{4-}$  at wavelengths shorter than 313 nm may be used to produce solvated electrons and the ferricyanide anion  $\text{Fe(CN)}_6^{3-}$ . The ferricyanide ion may subsequently be reduced at cathode back to the ferrocyanide anion:

$\text{Fe(CN)}_6^{3-} + \text{electron} \rightarrow \text{Fe(CN)}_6^{4-}$  (reaction at the cathode)  
[0222] Sulfite can also act as a sensitizer, especially at shorter wavelengths, for example, at 222 nm or 185 nm. In this case a solvated electron and the sulfite radical ( $\text{SO}_3^{\cdot-}$ ) are produced. The sulfite radical can dimerize and form dithionate  $\text{S}_2\text{O}_6^{2-}$  or undergo further reactions. Electrolytic reduction of these species can reduce the amount of sulfite required.  
[0223] A photo-electrolytic device can increase the efficiency of PFAS destruction in multiple ways. As mentioned above, the photo-oxidized sensitizer can be electrochemically reduced back to the sensitizer. A photo-electrolytic device can also reduce the presence of scavenging species. For example, oxygen is an efficient scavenger of solvated electrons and interferes with destruction of PFAS. Lowering the levels of oxygen would be useful. Oxygen levels can be reduced by electrochemically reducing oxygen to less reactive species like water. In this case, the electrolytic reaction could occur before and/or during the photolysis. The replacement of fluorine on PFAS for hydrogen requires two electrons. The mechanism is believed to involve two separate one electron reduction steps. One of these electrons could be provided by reaction with a solvated electron, in electrolytic device the second electron could be provided electrochemically.

[0224] In some embodiments, the anode may be comprised of a semiconducting polymer on a conductive substrate such as a metal or carbon electrode. For example, metals that oxidize to diamagnetic species that have an empty d-shell, such as  $\text{Al}^{3+}$  or one that is filled such as  $\text{Zn}^{2+}$  may be used. In some embodiments, a polymeric semiconductor may be coated on the anode to prevent diffusion of potential scavenging species which might compete with PFAS destruction. For example, the anode may be coated with oxidizable entities. Examples of oxidizable entities which may be used in various embodiments include  $\pi$ -conjugated polymers, including but not limited to polyacetylene, polyaniline, polythiophene, polypyrrole, poly(p-phenylene), poly(p-phenylene vinylene) and their derivatives, as well as polymers that are based on the reduced form of n-type semiconductor polymers or blends thereof. Examples include but are not limited to polymeric quinone (PQ), poly(5-amino-1,4-naphthoquinone) (PANQ), poly(2,5-dihydroxy-1,4-benzoquinone-3,6-methylene) (PDBM), poly(anthraquinonyl sulfide) (PAQS), poly(2-vinylanthraquinone) (PVAQ), polymer-bound pyrene-4,5,9,10-tetraone (PPYT), naphthalene diimide (PNDI) derivatives, pyromellitic diimides (PPMDI) derivatives, polylactam/lactone derivatives, polymeric isoindigo (IIG) derivatives, polymeric diketopyrrolopyrrole (DPP) derivatives and acceptor-acceptor derivatives. Another example includes polymers with oxidizable pendent groups including but not limited to ascorbic acid and alkali or alkaline metal salts of polymeric ascorbic acid, or anthracene, pyrene, naphthalene. The anionic forms of the semiconductors may be charge balanced by an alkali cation ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Rb}^+$ ) or alkaline metal ( $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{Ba}^{2+}$ ) or tetraalkylammonium cations in some embodiments. When the electrons are removed from the reduced form of the semiconductor, the cations are released into the solution. Some of the above undergo irreversible reactions but others can be recharged to the anionic state by electrochemical reduction. In the case of all the polymers with pendent units the linkage between the polymer backbone and the pendent group should not be hydrolysable under the photolysis condition which is generally at a high pH (>9). Examples of polymers which may be used in various embodiments are shown in FIGS. 10 and 11. FIG. 12 shows examples of structures of polymeric n-type organic semiconductors that may be used in embodiments of the present disclosure.

[0225] In some embodiments, the anode may be contained in an UV opaque material while still allowing contact with the wastewater that is being irradiated. This may be beneficial when organic semiconducting molecules are part of the anode to prevent unwanted photolytic reactions that could lead to the decomposition of the organic semiconductors and possible introduction of unwanted byproducts that could react with solvated electrons.

[0226] Other potential materials that may be coated or bound to the anode in various embodiments are polymeric alcohols and sugars that can be oxidized. Polymeric alcohols or sugars can be oxidized to aldehydes, ketones, carboxylic acids or carbon dioxide. In the case of polymeric alcohols or sugars, they may be consumed and may be viewed as sacrificial reductants. An example of a polymeric alcohol which may be used in various embodiments is polyvinyl alcohol.

[0227] In some embodiments, an oxidizable unit may be attached to polymeric alcohols such as polymer bound ascorbic acid, where the disodium salt would be oxidized to the corresponding dehydroascorbic acid form and the sodium would be released into the solution as shown in the reaction shown in FIG. 13. A water-insoluble ascorbic acid-containing polymer such as that disclosed in WO2000072959A1 may be used in various embodiments. This polymer acts as an antioxidant via the reaction of ascorbic acid units with oxidizing agents present in the environment. If used in a reaction solution, it can subsequently be removed from the solution by, for example, filtration. In some embodiments, a similar polymer can be used in conjunction with the UV-ARP process to reduce chemical compounds such as molecular oxygen and photosensitizer byproducts as defined previously.

[0228] In various embodiments, polymeric ascorbic acid and derivatives that are stable at high pH may be used. For example, in the chemical structure as shown in FIG. 14, the linking group X, may be selected from the following: oxy ( $\text{—O—}$ ), thio ( $\text{—S—}$ ), aza ( $\text{—NR.sub.1—}$ ) where R.sub.1 is a hydrogen, alkyl or aryl group, alkylene ( $\text{—(CR.sub.2R.sub.3).sub.n—}$ ), where R.sub.2 and R.sub.3 can independently be selected from hydrogen, hydroxy, alkyl or aryl, arylene, and aralkylene, an alkarylene, amide ( $\text{—C(O)NH—}$ ), or combinations thereof. The polymer may be selected from polyacrylates, polystyrenes, polyurethanes, polycarbonates, polyolefins, polypeptides, polyamides, polyethers, and siloxanes.

[0229] Other examples of polymers with oxidizable units which may be used in various embodiments are sulfur containing polymers, including but not limited to polyether-thioethers and polyethersulfones such as those shown in FIG. 15. One such example that may be used in various embodiments is a polymer designed to be used in lithium ion polymers as a polymer electrolyte as reported by Sarapas and Tew (Sarapas, J. M. and Tew, G. N.; Poly(ether-thioethers) by Thiol-Ene Click and Their Oxidized Analogues as Lithium Polymer Electrolytes; *Macromolecules* 2016, 49, 1154-1162).

[0230] Various shapes or structures may be used for the electrodes. For example, in some embodiments, the cathode may be a metal wire electrode. In other embodiments, the cathode may be a mesh structure, which may increase the surface area and allow for more efficient and uniform capture of the photo-generated products. The materials for this electrode may include, for example, high density graphite, platinum, gold or other non-kinetically reactive conductors. In some embodiments, metals like iron, zinc or aluminum could be used, depending on the pH.

[0231] Recycling sensitizer. As discussed above, in the advanced reductive process (ARP) solvated electrons are generated by UV irradiation of a sensitizer. A common sensitizer is iodide, with UV light generating a solvated electron and iodine radical. The solvated electron reacts with the PFAS molecule. However, two iodine radicals can combine and form iodine, and iodine and iodine radicals can react with solvated electrons. So, if the iodine concentration builds up, the destruction of PFAS may be impaired. One solution to this problem which may be used in various embodiments is the inclusion or addition of millimolar sulfite to the reaction mixture. The sulfite reduces the iodine or iodine radicals back to iodide. The sulfite eventually reacts to form sulfate that does not interfere with the photochemical destruction of PFAS. The use of sulfite is a good

solution; however, high concentrations of sulfite also react with solvated electrons and there are chemical biproducts.

[0232] In alternative embodiments, electrochemical reduction of iodine or iodine radicals may be used to prevent interference with the destruction of PFAS. As compared to processes which use sulfite as discussed above, the use of electrochemical reduction allows the use of lower concentrations or no sulfite. Although electrochemistry involves generating oxidized species at the anode, the oxidation and reduction can be performed in separate compartments of the photo-electrolytic device, and therefore the oxidized species do not interfere with PFAS destruction. For example, as shown in FIG. 16 photolysis and iodine reduction may occur in one compartment, while oxidation may occur in a separate compartment with the compartments separated by a membrane or ionic bridge. If water is oxidized, the chamber could be sparged with an inert gas like argon or nitrogen, which would prevent the oxygen from getting into the compartment where photolysis and reduction are occurring.

[0233] An example of the electrochemical regeneration of oxidized iodide is shown in FIGS. 17 and 18, using a system like the one shown in FIG. 9. At one electrode the iodine radicals generated by photo-oxidation of iodide are reduced back to iodide. At the other electrode, an oxidation process occurs. In aqueous media water can be oxidized to oxygen and provide electrons. Other examples of species that can act as reductants are sulfite, iodide, ascorbic acid or ascorbate can also act as reductants.

[0234] Solvated electrons. In some embodiments, an electrochemical system may be used to modify the local pH of the solution as shown in FIG. 19. Electrolysis of water at the cathode causes the pH to increase. High pH is generally desirable for the destruction of PFASs by solvated electrons because the hydrogen ion ( $H^{+}$ ) rapidly reacts with solvated electrons. The pH is lowered in the vicinity of the anode. Therefore, if solvated electrons are generated near the cathode, they have sufficient lifetime to react with PFASs. One possible configuration is to have a light source that is irradiating a semiconductor such as a diamond-like carbon or boron-doped diamond in close proximity to the cathode. Systems like this have the advantage of requiring minimal salt concentrations and minimal pH adjustments.

[0235] In some embodiments, boron-doped diamonds may be used as an electrode and the source of solvated electrons when irradiated by sufficiently energetic UV photons. Hydrogen-terminated diamonds have been considered to be preferred diamonds to use for UV generation of solvated electrons. This is because they are negative electron affinity materials. Electrolyzing water causes an increase in the pH around the cathode. Irradiation of the boron-doped diamond at the cathode may be used, resulting in generation of solvated electrons that are sufficiently long-lived to react with PFASs.

[0236] Doped-diamonds may be used to generate solvated electrons, the hole that is formed on the diamond can be electrochemically reduced. The doped-diamonds used in various embodiments may have another atom incorporated into the diamond structure at the time it was synthesized.

[0237] For example, in some embodiments, solvated electrons may be generated by irradiating hydrogen-terminated diamonds, such as those described in “Degradation of perfluorooctanoic acid with hydrated electron heterogeneous catalytic system”, Liu, G.; Feng C.; and Shao, P.; Environ. Sci. Technol. 2022, 56, 6223-6231. In this process, UV light may be used to promote an electron from the valence band to the conduction band of the diamond. The electron is emitted into the aqueous solution. The solvated electron can then react with PFAS. For example, in some embodiments, the diamond may be irradiated in one compartment of an electrochemical cell. The other compartment may contain iodide and may be connected to the first compartment by a cation exchange membrane. As the photolysis proceeds, the solvated electrons generated from irradiation of the diamond react with the PFAS and the electron “holes” in the valence band of the diamond are reduced by the reaction of iodide to iodine at the electrode. This is an example of a galvanic device. However, the iodine will build up in the cell and eventually diffuse across the membrane

barrier since it is neutral and wouldn't be impeded by the membrane. An improvement to this is to irradiate the diamond while applying a voltage across the two electrodes such that protons are reduced to hydrogen at the cathode which results in an increase of pH around the cathode. A higher pH at this electrode will allow the photochemically generated solvated electrons to live longer and have more time to react with PFAS. At the electrode in the second compartment, an oxidation reaction occurs. In one embodiment, water can be oxidized to oxygen which may be removed by sparging the compartment with an inert gas (e.g. argon or nitrogen). Other species can also be added to this chamber to reduce the potential. These species include but are not limited to sulfite, iodide, ascorbate, ascorbate anions and easily oxidized metal ions.

#### 185 nm Hydroxyl Radical Generation

[0238] In some embodiments, gases such as hydrogen may be generated by electrolysis of water. Hydrogen gas can be used in conjunction with vacuum UV photolysis to greatly enhance the degradation of PFASs.

[0239] Irradiation of water solutions containing PFAS with 185 nm UV light results in modest degradation of PFAS through the generation of hydroxyl radicals. However, hydroxy radicals do not efficiently react with PFAS. Therefore, in some embodiments, 185 nm irradiation of an aqueous solution of PFAS to form hydroxyl radicals may be used with concurrent electrochemical generation of hydrogen gas. In such embodiments, the 185 nm irradiation of water results in generation of hydroxyl radicals in the presence of hydrogen gas in the aqueous PFAS solution.

[0240] Under basic conditions hydrogen gas reacts with hydroxyl radicals to form hydrogen atoms and water, and the hydrogen atoms produce solvated electrons. This combination of electrochemical generation of hydrogen gas in water and irradiation of water with 185 nm light to produce hydroxyl radicals may be used in various embodiments for more efficient PFAS destruction process.

[0241] Producing hydrogen gas through electrolysis according to various embodiments avoids the need to separately provide hydrogen gas to saturate the solution. In addition to being more complicated, such a process would include the use and storage of a highly flammable substance. Rather, by generating hydrogen gas electrochemically using the methods described herein, the hydrogen gas may be produced in close proximity to where the light is being absorbed, such as less than 2 cm, or between about 0.5 and 2 cm, or about 1 cm.

[0242] For example, in some embodiments, a photo-electrolytic cell may be used like that shown in FIG. 20. The light source, such as a 185 nm light source, may be placed in a test tube or other transparent container, and submerged in the PFAS solution. An electrode may be wrapped around the test tube, such as about 1 cm from the test tube. A voltage sufficient to produce hydrogen gas may be applied across the electrode. This electrode is electrically connected to the electrode in the separate compartment, where oxidation occurs. If water is the reductant oxygen is the product. The electrode may be a mesh, for example. The electrode may be platinum, titanium, or stainless steel, for example. In some embodiments, the electrode may be platinum coated titanium, such as a platinum coated titanium mesh. For example, the cathode may be made of a high surface area construction, such as a mesh or foam, in which the electrochemically active surface area is greater than the geometric surface area. Other electrodes described elsewhere in this disclosure may also be constructed in these ways.

[0243] After the photolysis is complete, the excess hydrogen can be electrochemically oxidized to make water by reversing the flow of current to reverse the electrochemical process.

[0244] Vacuum Ultraviolet (VUV) is defined as the portion of the electromagnetic spectrum between 100-200 nm. Mercury lamps can emit in this region at 185 nm. As shown in FIG. 21, water absorbs at 185 nm radiation and can be broken apart into hydrogen radicals and hydroxyl radicals with a quantum efficiency of ~0.3; hydroxide also absorbs 185 nm light and generates the hydroxyl radical and a solvated electron with a quantum efficiency of ~0.1. In addition, water can absorb 185 nm radiation and form a hydroxyl radical, solvated electron and a proton with a

quantum efficiency of  $\sim 0.045$ .

[0245] In various embodiments, hydrogen gas may be electrochemically generated by electrolysis of water in close proximity to where the UV light is being absorbed. A consequence of electrochemically generating hydrogen at the electrode is an increase in pH. This system does not require an external source of hydrogen. It allows for the construction of a simple, inexpensive device that does not require added chemicals, like hydrogen or sulfite. In addition, any excess hydrogen can be reacted with oxygen after the photolysis is completed.

[0246] The electrolysis of water can be continuous or intermittent during the photolysis process. At high pH, such as a pH of 9-12 an intermittent electrolysis process might be sufficient, where the main effect is providing a high concentration of hydrogen gas. Continuous electrolysis may be preferred at neutral pH s, such as pH s of 6-8, because electrolysis will raise the pH in the volume around the electrode. In some cases, it would not be necessary to adjust the pH. However, in some embodiments, the pH may need to be raised, such as through the addition of a base, such as if the pH is less than about 6.

[0247] The above method provides a process for destroying PFAS with minimal additives. As such it may be useful as a device that could treat drinking water to remove PFAS, such as in the form of a self-contained unit for home use that could be operated by connecting to a power source like a power outlet, and the household water supply. Alternatively, it could be used in conjunction with an RO system to destroy the PFAS of the RO reject. Such a system could be deployed at small commercial or residential locations. The main biproducts of the reaction would be free fluoride and carbon dioxide as well as hydrogen and oxygen from the electrolysis reaction. Free fluoride levels could be controlled by treating the water with lime or bone ash. Hydrogen and oxygen could be combined to produce water.

[0248] Non-mobile media reduction of byproducts. A non-electrochemical method which may be used in various embodiments includes utilizing polymeric species as non-mobile media that can reduce oxidized byproducts of the photochemical reaction back to the original sensitizer such as iodide. The non-mobile media may include beads or membranes or other structures, for example, that have polymerically bound reducing agents. For example, in the case of iodide as the sensitizer, the oxidized byproducts (iodine radical, iodine or triiodide) can react with a polymeric ascorbic acid which may be used as the polymerically bound agent in various embodiments. Less salts, like sodium sulfite, would be required in such embodiments and the polymer-bound ascorbate and oxidized form may be physically separated from the photolysis reaction. In FIG. 22, one possible configuration is shown. The photolyzed solution is pumped through a cartridge containing a reducing species that can reduce the photooxidized sensitizer back to the sensitizer. The polymer bound reductants are physically separated from scavenging solvated electrons and therefore cannot react with solvated electrons. For example, the solution that is being irradiated could be pumped through a container containing a material capable of reducing iodine back to iodide. Many of the previously mentioned polymeric semiconductors may also be included to reduce the sensitizer byproducts back to the sensitizer. Preferred semiconducting polymers would be capable of being chemically or electrochemically regenerated and therefore allowing reuse of these materials in subsequent photolysis runs. Another example of a polymeric media that may be used in various embodiments to reduce the iodine radical, iodine or triiodide back to iodide are polymeric ferrocenes, for example polyvinylferrocene, shown in FIG. 23, or polymers that are based on the reduced form of n-type semiconductor polymers or blends thereof as listed above. Alternatively, the reduction of these species could be accomplished by a metal like zinc or aluminum or metal alloy in some embodiments. For example, the solution could be pumped through a column containing metal shot. In the case of metals, the metal ions that may be generated from the process should not act as scavengers of solvated electrons.

[0249] Another example of polymeric radical scavengers that may be used in various embodiments are polymers that can undergo red/ox reaction, such as polymers that contain a stable radical. One

example is polymers with tetramethylpiperidine 1-oxyl (TEMPO) side chains, as shown in FIG. 24. [0250] Oxygen reduction. In some embodiments, the UV reactor may contain one or more electrochemical systems for one or more functions (such as removing impurities in the water, removing or recycling photoproducts, and/or local pH modification). For instance, dissolved oxygen in water could compete with sensitizer in scavenging the hydrated electron, thus it may be removed in some embodiments. In an electrochemical system according to various embodiments, several cathode-driven O<sub>2</sub> reductions reactions (ORR) can be achieved such as:

[0251] Alternative solvents. In some embodiments, destruction of PFASs may be performed using solvents other than water. Some such embodiments may use electrochemistry in polar aprotic solvents to generate a highly reduced or oxidized species that can be subsequently photolyzed to generate other highly reactive species. Examples of aprotic polar solvents that may be used in various embodiments include acetonitrile, pyridine, dimethylsulfoxide, N,N-dimethylformamide, acetone, ethyl acetate, oxalane/tetrahydrofuran and crown ethers. For example, aromatic species like dicyanoanthracene (DCA) which may be used in various embodiments can be reduced to a radical anion (DCA<sup>•-</sup>) electrochemically and then be irradiated to generate an even more powerful reductant, the dicyanoanthracene radical anion excited state (DCA<sup>•-</sup>\*). Other aromatic species that can be used are 2,6-diisopropylphenyl-naphthalene and perylene bisimide. Since many of the radical anions which may be used in various embodiments absorb in the visible region or near UV region of the electromagnetic spectrum, this approach has the potential advantage of allowing lower energy (less than UV-C) to make very reactive species. It also may allow for the more complete absorption of the lamp energy if used in conjunction with a higher energy photon. An example of a process including aromatic compounds is shown in FIG. 25.

[0252] In some embodiments, the photochemical reactor may be equipped with the electrochemical system to decompose other recalcitrant pollutants such as pharmaceuticals, hormones, pesticides, antibiotics and cleaning solvents.

#### Post-Treatment Steps

[0253] Following the photochemical destruction of PFAS, it may be desirable to further treat the solution before final disposal or recycling of the photolyzed wastewater. A potential posttreatment scheme is shown in FIG. 26. In some cases, all these steps might be followed. In other instances, only one or some might be required. The post treatment steps may be performed sequentially and, in some cases, a given process could be perform more than one of these functions at once.

[0254] Post treatments used in various embodiments may depend on the outlet of the treated water. In some industrial settings, it might be desirable to reuse or reclaim the water. In other cases, the treated water might be returned to the environment. In other cases, the water might be allowed to evaporate or subject to incineration. The goal of the post treatment may be to condition the water to a specification for reuse or to meet regulatory or anticipated regulatory requirements. In other cases, some of the photochemically treated water may be treated with a membrane where the membrane reject (water that does not pass through the membrane) is circulated back into the photoreactor for further treatment.

[0255] The schematic shown in FIG. 26 presents the steps of a possible posttreatment process. For some scenarios, it might be necessary to perform all the steps outlined. For many scenarios, only some of the posttreatment steps would be required. In many embodiments, adjusting the pH to 6-8 will be required.

[0256] The sensitizer may be the most expensive reagent used in the photoreduction step, so it may

be desirable to recover it or a material that could be readily converted to it. In the case where iodide is the sensitizer, one useful way to capture the iodide is to electrochemically reduce the iodide to iodine or a polyiodide in a specific electrode. To recover the iodide, the captured polyiodide can be reduced either electrochemically or chemically from the iodine-containing electrode. To accomplish this, it may be preferred to lower the pH to between 5-8 because iodine and polyiodide are susceptible to other reactions at high pH. Excess sulfite may potentially reduce the efficiency of the electrochemical process, therefore, a step involving destruction or removal of the sulfite prior to sensitizer recovery may also be preferred.

[0257] For some applications, recovering the iodide may not be economical, however, it still may be necessary to remove the iodide from the final treated water. In this case, adjusting the pH and then running the solution through one or more anion-exchange media could remove iodide, fluoride, sulfite or sulfate. A final polishing step, such as a GAC treatment, may then be used to lower iodide further, such as to meet the recycled water specification or regulatory requirements.

[0258] In some embodiments, all anionic constituents including sulfite, iodide, sulfate and fluoride could all be removed simultaneously by an anion exchange media with or without pH adjustment, such as a means of direct polishing of the photochemical treated water.

[0259] In some embodiments, the photochemical treated water may be removed by evaporative processes such as thermal vaporization or spray drying and the ions and their salts recovered by precipitation.

[0260] A potentially lower cost but more time-consuming post-treatment which may be used in various embodiments includes reducing the pH and then precipitation, such as of the fluoride and sulfate, by adding lime and allowing the solids to settle and clarify. The clarified water could then be passed through a final polishing step, such as running through a GAC bed or subjecting it to RO.

[0261] To put PFAS containing water back into the environment, these molecules would have to be removed to the appropriate level to comply with existing regulations for allowable concentration of some PFAS molecules. The photoreduction process may be successful at destroying most of the regulated PFAS, however, some small amounts of new PFAS and polyfluorinated may be generated. These molecules, currently, do not have specified limits. In the future, regulations could change to include these materials. One option to eliminate these materials that may be used in various embodiments is by doing a thermal oxidation process with persulfate as a post-treatment step. Alternatively, or additionally, an electrolytic process may be used to reduce or eliminate these materials. Another method which may be used in various embodiments, alternatively or additionally, is nucleophilic displacement of fluorine atom from these molecules to increase the amount of free fluoride and reduce the levels of PFAS and polyfluorinated species. These post treatments can result in near complete destruction of materials containing carbon-fluoride bonds.

[0262] Various UV-ARP processes may be performed at a high pH which is very caustic.

Therefore, in some embodiments, the post-treatment solution may involve lowering the pH to 6-8. by addition of acid. In addition to making the solution less caustic, some of the subsequent post-treatment steps are more effective at lower pH.

[0263] Various UV-ARP processes use a sensitizer and a sacrificial electron donor. For example, the sensitizer for UV-ARP at 254 nm may be iodide and the sacrificial donor may be sulfite. At shorter wavelengths, for example 254 nm and 185 nm, sulfite can also be an effective sensitizer. Excess sulfite can be converted to sulfate by oxidation with air, oxygen or peroxides or electrochemical. UV light can be used to accelerate the oxidation of sulfite to sulfate. However, as discussed above, sulfite may be an impediment to recovering oxidized iodide species such as iodine, triiodide or other polyiodides. Therefore, it may be preferable in some embodiments to reduce or eliminate the sulfite prior to electrochemical recovery of iodide species from the post-treatment solution.

[0264] The sensitizer is often the costliest reagent in ARP. Iodide salts are often used as a sensitizer. Therefore, methods to recover the iodide such as those disclosed above are desirable.

[0265] Iodine recovery. In some embodiments, iodide may be recovered by iodide-specific anion exchange membranes (AEMs). In some embodiments, the AEM can be used in conjunction with an electrochemical cell for iodine-iodide recycle and recovery.

[0266] In some embodiments, the photolysis condition may require a high pH, a sensitizer and one or more inorganic salts. The photochemical destruction of PFAS results in formation of the fluoride ion. In order to remediate the water and recover high value materials, further processes may be used. For example, in one embodiment in which iodide is used as a sensitizer, the iodide may be oxidized to iodine which is relatively insoluble in water. The iodine could be precipitated and recovered by filtration. However, in some cases, the iodine concentration is low enough that all the iodine is left in the solution. In this case, a precipitation process would be ineffective. Also, iodine is unstable at high pH. Therefore, some embodiments may further include lowering the pH to between 3-8, or 5-7, to more fully recover iodine. The pH could be lowered by use of a suitable acid, like a mineral acid.

[0267] Sulfite also reduces iodine back to iodide. To enable the recovery of photosensitizer species in various chemical forms such as iodide, separation processes to isolate the photosensitizer from other constituents such as sulfite may be employed. These processes include but are not limited to ion exchange membranes, ion selective resins, and size exclusion materials.

[0268] In some embodiments, such as embodiments in which sulfite is present, post processing may be performed to transform the sulfite to sulfate. For example, sulfite may be converted to sulfate by the addition of a suitable oxidant to the reaction solution after UV treatment. Examples of oxidants that may be used in various embodiments include air, oxygen, and/or hydrogen peroxide, for example. Oxygen or air may be preferred in some embodiments because they oxidize sulfite but do not oxidize iodide and therefore may be used in excess concentration. Other oxidants may alternatively or additionally be used in some embodiments to selectively remove sulfite. In some embodiments, the post photolysis process of transforming sulfite to sulfate may be accomplished or accelerated by the addition of catalysts or electrochemically.

[0269] In some embodiments, the iodine species may be recovered by adding a tetraalkylammonium salt, like tetraalkylammonium hydroxide which may directly precipitate the iodide ion and form a tetraalkylammonium iodide. In other embodiments, iodide could be removed through complexation with a quaternary ammonium or other cationic polymer. Furthermore, cationic polymer materials could be blended with an electrode coating. However, tetraalkyl ammonium cations may be prone to degradation in strong alkaline conditions due to their propensity towards Hofmann elimination among other degradation pathways. Therefore, the cationic unit may be chosen from those with proven stability. These include but are not limited to alkyltrimethylammonium cations where alkyl chain is longer than 4 carbons, cyclic ammonium cations, and imidazolium cations. Other cation centers that may be used include phosphonium, cobaltocenium, and ruthenium cations.

[0270] In some embodiments, after the sulfite is transformed and/or removed, the iodide may be oxidized to iodine which could precipitate. The precipitated iodine may then be collected. In some embodiments, the iodine may be precipitated electrochemically in a module that could be removed or the iodine recovered and then reused. A similar sequence of reactions could be used to recover pseudo-halogens species that may be oxidized to a neutral, insoluble species in aqueous media.

[0271] Various embodiments include processes for allowing the efficient destruction of PFAS materials including the use of an electrochemical system to convert the reaction products of UV sensitizer back to the original sensitizer. For example, in some embodiments, iodine species may be recovered from the photolyzed solution by electrochemical means.

[0272] For example, some methods for recovering iodine species from aqueous solutions include electrochemical oxidation of an aqueous solution containing iodide to iodine species such as the triiodide ion or other polyiodide anion. Polyiodides are a class anion composed entirely of iodine

atoms. The most common member is the triiodide ion, I<sub>sup.-</sub>.sub.3. Other known polyiodides include [I.sub.4].sup.2-, [I.sub.5].sup.-, [I.sub.6].sup.2-, [I.sub.7].sup.-, [I.sub.8].sup.2-, [I.sub.9].sup.-, [I.sub.10].sup.2-, [I.sub.10].sup.4-, [I.sub.11].sup.3-, [I.sub.12].sup.2-, [I.sub.13].sup.3-, [I.sub.14].sup.4-, [I.sub.16].sup.2-, [I.sub.22].sup.4-, [I.sub.26].sup.3-, [I.sub.26].sup.4-, [I.sub.28].sup.4- and [I.sub.29].sup.3-. All these may be formed from the interaction of the I<sub>sup.-</sub>, I<sub>sub.2</sub>, and I<sub>sup.-</sub>.sub.3 building blocks.

[0273] In some embodiments, electrochemical oxidation of iodide may include the use of an iodophilic electrode, such as an electrode including 1) an iodophilic material which has an affinity for iodide, iodine, or a polyiodide, 2) an electrically conductive material and 3) a binder material to provide mechanical and chemical integrity to the electrode. The iodophilic material may be, for example, anion exchange resins, starches and/or inorganic or organometallic complexes that form iodide or polyiodide salts. The conducting material may be, for example, graphite, graphene, carbon nanotubes, and/or a conducting polymer or metal. The iodophilic material may be present in a range of about 20% to about 70% of the combined electrode material. The electrically conductive material may be present in a range of about 10% to about 60% of the combined electrode material. The binder material may be present in a range of about 20% to about 50% of the combined electrode materials. For example, in some embodiments, the iodophilic material may be about 35 to about 60%, the electrically conductive materials may be about 20% to about 50%, and the binder material may be about 30% to about 50% of the electrode material.

[0274] The iodophilic material may be used to concentrate and immobilize the iodine containing species present in the treated solution after UV-ARP during post-treatment. The conductive material may be used to allow for efficient transport of electrons throughout the electrode composition. The binder may be used to provide chemical and mechanical integrity to the electrode. In some embodiments, an electrically conducting material may be used which acts both as a conductor and a binder. In some embodiments, an iodophilic material may be used which is also conductive, such as conductive polymers like polyaniline. In such embodiments, the electrode may include only two components.

[0275] The binder material may provide the electrode with mechanical integrity, supporting the electrochemical processes. The iodophilic material and conductive material may be organic or inorganic powders, for example, and therefore the binder material such as a polymer may be needed to maintain the structural integrity of the electrode and make the electronic network continuous by binding the active material and conducting additives together. In addition to binder materials such as polymers holding the active materials and conductive agents together, it can also function to adhere the electrode to a current collector. In addition, the binder material may facilitate the formation of electron and ion circuits to guarantee the electrochemical reaction by providing good mechanical integrity to support electrical conductivity. The iodophilic electrode can be free-standing construction (electrically connected but without a current collector) or attached or bonded to a current collector.

[0276] Examples of binding materials which may be used include, but are not limited to, polyvinylidene fluoride (PVDF) and/or styrene butadiene rubber (SBR). PVDF synthesis may be usually done by emulsion polymerization or suspension polymerization process, for example, such as commercially available materials HSV900 (from Arkema) and 5130 (from Solvay), made by the two methods, respectively. Other binder materials that may be used include polytetrafluoroethylene (PTFE). Many of the binders used in lithium-ion battery cathode constructions could also be used for this application.

[0277] The purpose of the iodophilic material in the electrode, having a high affinity for iodine/iodide/polyiodide, is to interact with some or all of the iodide species in the treatment solution and immobilize them in or on the electrode. These iodine-containing species can exist in equilibrium with each other. Therefore, materials that can interact with iodine, iodide or a polyiodide species can be useful. For example, to capture iodide, an anion exchange membrane

would be effective. Anion exchange membranes are crosslinked polymers that have low solubility. Iodine is a Lewis acid and, as such, it can form complexes with electron donors.

[0278] One method to reduce the solubility of various iodophilic polymers in aqueous media is by crosslinking the material. Many polymers can be used, for example, starches and other polymeric sugars are known to have a strong affinity for capturing the triiodide anion. Starches can be crosslinked with epichlorohydrin or 2,3-epoxypropyltrimethylammonium chloride. For example, in some embodiments, membrane materials might help capture iodide at the electrode where it can be reduced. In some embodiments, starches may be used which may be crosslinked to be water soluble.

[0279] Iodine forms strong iodine complexes with crosslinked cationic starch derivatives N-(2-hydroxyl)propyl-3-trimethylammonium chloride, and this material may be used as the iodophilic material in various embodiments. The starches could be crosslinked starched or could be crosslinked during the ball-milling or formulation step, for example. Other iodophilic materials which may be used in various embodiments include crosslinked polyvinyl alcohols (PVAs), chitosan, cellulose, some derivatives of cellulose, crosslinked copolymers of N-vinylpyrrolidone (N-VP) and/or copolymers of polyethylene glycols. A water-soluble chitosan may be used, with the solubility determined or adjusted by the extent of deacetylation, the pH and the degree of crystallinity. One consideration for the selection of the iodophilic material is that it have limited solubility in the aqueous solution under the time frame of the electrodeposition process.

[0280] Other possible materials with high affinity for iodide that may be used as the iodophilic material in various embodiments include metallocene such as ferrocene and its substituted derivatives or polymeric ferrocenes such as polyvinylferrocenes, all of which form triiodide salts. In still other embodiments, the materials used in organic semiconductors, for example, polythiophenes, polypyrroles and polyanilines, which can form polyiodide salts, may also be used as iodophilic material. One iodophilic material may be used in the electrode or a combination of two or more materials, such as those listed herein, may be used in various embodiments.

[0281] Various systems and methods may use the iodophilic electrode for the recovery of iodine species from an aqueous solution where iodide serves as a photosensitizer in an advance reductive process (ARP) used to generate solvated electrons in the destruction of PFAS compounds. These systems and methods are particularly useful for cost reduction since the photosensitizer is often the most expensive reagent in UV-ARP processes. The use of an iodide recovery electrode allows the iodide to be isolated from the other photochemical biproducts and reused in additional subsequent cycles of UV-ARP with different batches of wastewater.

[0282] Unlike methods of iodine recovery used in other settings, such as through the use of a polyhalide ion exchange resin using bromine or chlorine, no such additional highly reactive species need to be added using the iodophilic electrode for iodine recovery as taught in this disclosure. Similarly, methods of halide recovery that use electrochemical oxidation cause the iodide to precipitate at the electrode where it is then collected as a solid. In contrast, the process disclosed herein using the iodophilic electrode result in the capture of iodide/triiodide/polyiodide in the volume of the electrode. The electrode may then be removed, and the iodide can be released by electrochemical reduction using a current in the opposite direction.

[0283] The systems and methods may be used with treated solution having any concentration of iodide, though lower concentrations may have lower rates of oxidation and therefore require longer electrolysis times. Iodide concentrations above 1 mM may be preferable. In some embodiments, an anion exchange material might be used to concentrate the iodide near the electrode. In some embodiments, the time to capture the iodine may be reduced by increasing the surface area of the electrode. Molecular Iodine, and therefore triiodide and polyiodide, form more readily in neutral and acidic pH, so an operating pH below pH 9 is preferable. Various embodiments include adding acid to treatment solutions having a basic pH to bring the pH of the treatment solution below about 9, such as between about 4 and about 9, or between about 5 and about 9. It is also useful if the

iodide containing treated solution has adequate conductivity to minimize the over potentials needed for iodide oxidation. Therefore, in various embodiments, a total electrolyte concentration above about 10 mM is preferable, and higher concentration such as above about 100 mM may be useful to achieve rapid iodide oxidation. If the solution does not already contain adequate electrolyte concentrations, an electrolyte that does not interfere with the oxidation reaction may be added. For example, various embodiments may include adding suitable electrolyte such as Na<sub>2</sub>SO<sub>4</sub>, K<sub>2</sub>SO<sub>4</sub>, NaCl, and/or KCl, among others, among others, to increase the conductivity before iodide recovery using the iodophilic electrode.

[0284] When preparing the treated solution for iodide recovery, it may not be necessary to adjust the pH for iodine stability, as iodide is stable in all pHs. However, the pH may impact the chemical stability of the electrode, depending upon the composition of the electrode. While many of the conductive materials and the binder materials used in the electrode may have good chemical stability, the iodophilic material used in the electrode may be sensitive to pH, and therefore pH may need to be adjusted depending upon the choice of the iodophilic material and the pH of the treated solution. In some embodiments, the iodophilic electrode may be used in treated solutions having a near neutral pH, such as a pH from about 6 to about 8, to provide good chemical stability. The treated solution may be adjusted through the addition of an acid or base to achieve this pH range prior to post-treatment using the iodophilic electrode.

[0285] In various embodiments, to avoid competition from water oxidation and water reduction, the iodophilic electrode may be operated in a voltage range in which water oxidation or water reduction are not present. For example, in a solution having a pH of about 7, a voltage range of about -1.0 to about 1.2 V vs Ag/AgCl is appropriate and may be used in various embodiments. When the solution has a higher pH, the voltage range used may shift by -0.059 V with each one point increase in pH value. When the solution has a lower pH, the voltage range used may shift by +0.059 V with each one point decrease in pH value.

[0286] The electrode may be used in either a galvanostatic or potentiostatic condition, for example. In methods and systems using a galvanostatic operation, a constant current is applied to the electrode. A range of 0.1 to 10 mA/cm<sup>2</sup> may be for oxidation and -0.1 to -10 mA/cm<sup>2</sup> may be for reduction, to balance speed and efficiency, though lower or higher ranges could alternatively be used. The reaction may continue until the total charge passed is sufficient to substantially or to fully load/unload the electrode and then may be stopped, for example. Alternatively, the reaction may continue until the voltage reaches a cut off limit that is set before beginning the reaction, such as in order to avoid performing water oxidation or reduction, and then may be stopped, for example. In potentiostatic operation a constant potential may be applied to the electrode. A potential may be chosen that is sufficient to oxidize iodide to triiodide/polyiodide without inducing water oxidation for the anode and a potential may be chosen that will be sufficient to reduce triiodide/polyiodide to iodide without inducing water reduction for the cathode, as described above.

[0287] The above electrode may be part of an electrochemical device. The electrochemical device may include an anode chamber that contains iodide, such as iodide in a post UV-ARP treated solution, and a cathode chamber that does not contain iodide separated by a cation exchange membrane. In the anode chamber an oxidizing current is applied to the electrode described and the iodide is oxidized to triiodide/polyiodide which is immobilized in the electrode. In the cathode chamber a cathodic current is applied to the iodide capture electrode that has been loaded with triiodide/polyiodide causing the triiodide/polyiodide to be reduced to iodide that is then released into solution.

[0288] Various embodiments of the cell include a two-electrode system in which an unloaded iodide capture electrode is used as the anode and a loaded iodide capture electrode is used as the cathode. An example of an electrolytic system that may be used for iodine recovery is shown in FIG. 27. This example includes a two-electrode system in which an iodide recovery electrode is

used for both the cathode and the anode. In this system an iodide recovery electrode that has previously been loaded with triiodide/polyiodide is used as the cathode, and an iodide recovery electrode that is empty is used as the anode, for example. The cathode is placed in an iodide recovery solution that does not initially contain iodide at the start of the electrolysis. The anode is placed in an iodide containing solution. A current is applied to the electrodes from an external power supply such that triiodide/polyiodide is reduced to iodide at the cathode, and iodide is oxidized to triiodide/polyiodide at the anode. During electrolysis the concentration of iodide in the cathode chamber increases as it is released from the cathode, and the concentration of iodide in the anode chamber decreases as it is stored in the anode in the form of triiodide/polyiodide. When the reaction is complete, electrode B will be depleted of triiodide/polyiodide and will be placed into a new iodide containing solution where it will act as an anode, and electrode C will be fully loaded with triiodide/polyiodide and will be placed into a new iodide recovery solution where it will act as a cathode. In this way, there is recovery of iodide from an iodide containing solution.

[0289] Various embodiments of the cell also include a three-electrode system in which an iodide recovery electrode is used as the working electrode (WE), a stable metal (e.g. Pt, Ir, Ti, etc.) is used as the counter electrode (CE), and Ag/AgCl, is used as the reference electrode (RE), though other materials such as a calomel electrode or Hg/HgO electrode could alternatively be used. In this system the iodide recovery electrode is first used as an anode in an iodide containing solution, such as a treated solution after UV-ARP, by applying a controlled voltage between the WE and RE to oxidize iodide to triiodide/polyiodide. The CE and the RE may both be in water, and the CE will perform water reduction to balance the current flow. When the iodide recovery electrode is loaded with triiodide/polyiodide the WE chamber is switched to an iodide free solution. The WE is then used as a cathode to reduce the immobilized triiodide/polyiodide to iodide that is released into the recovery solution. The CE will perform water oxidation. Sacrificial oxidants (e.g. O<sub>2</sub>) and reductants (e.g. sulfite) may be added to the CE chamber to lower the required cell voltage.

[0290] In some embodiments, an alternative iodophilic electrode may be used. The electrodes may be a double-layered cathode having a first layer formed of a conductive material and a second layer in contact with the first layer, where the second layer adsorbs a triiodide ion and where the triiodide ion is reduced at the interface between the first and second layers. The first layer may include a two-dimensional carbon structure such as graphene or a carbon fiber cloth. The second layer may contain at least a polypyrrole, a polyaniline or poly(3,4-ethylenedioxythiophene), for example.

[0291] Various embodiments include an iodide/iodine/triiodide/polyiodide specific electrode, and methods and devices for capturing and/or recycling iodide/iodine/triiodide/polyiodide from aqueous media, such as capturing and recycling iodide/iodine/triiodide/polyiodide back into a photochemical reactor for repeated use in UV-ARP.

[0292] In some embodiments, iodine may be recovered from the post treatment solution by flowing the solution through a module containing an anion exchange media that would complex with the iodide. This step may be done after pH adjustment and sulfite removal as discussed above, for example. The pH may be lowered through the addition of acid to a range of about 4 to about 9, or about 5 to about 9, for example.

[0293] In other embodiments, an anion exchange membrane can be used to recover iodide. For example, strong anion exchange resins, containing quaternary ammonium groups, may be used in various embodiments. Two types of anion exchange membranes which may be used include Type I resins which contain trialkyl ammonium chloride or hydroxide and Type II resins which contain dialkyl 2-hydroxyethyl ammonium chloride or hydroxide. Some examples of these resins are Dowex 1X2, Dowex 1X4, Dowex 1X8, Dowex 2X8-100, 2X8-200 and 2X8-400. Weak anion exchange resins, which lack exchangeable ions, may also be used.

[0294] For example, in some embodiments, after photolysis, the pH may be adjusted and then the solution may be passed through or allowed to flow through the ion exchange membrane, whereupon the iodide is bound to the membrane. The iodide may then be released by following a

solution of a salt such as a sodium chloride solution through the membrane to release the iodide back into solution. The solution containing the released iodide may be added to the UV-ARP reactor for reuse. Therefore, the salt should be chosen such that it will not interfere with subsequent photochemical reactions. Suitable salts which may be used in various embodiments include sodium chloride, sodium bromide, potassium chloride, potassium bromide, sodium hydroxide, potassium hydroxide, and/or sodium sulfate, for example. Unsuitable salts would contain species that have a high affinity for solvated electrons or strong absorption in the UV between 180 nm and 400 nm. Sodium nitrite and sodium nitrate are two examples of unsuitable salts to displace the iodide because nitrates absorb in the UV and also react with solvated electrons.

[0295] The concentration of the salt solution may be chosen such that it is high enough to release the iodide back into the solution. The affinity for various anions for both type I and type II resins are known. The necessary concentration of salt can be determined by relating the relative affinity for iodide and the salt of choice, and then comparing it to the iodide concentration of the starting solution.

[0296] PFAS removal. In some embodiments, such as where further reductions in the PFASs concentration are required before release of the treated wastewater, for example, to meet the stringent EPA limits, the photochemically treated liquid may undergo one or more further post-treatment processes to further reduce the level of PFAS. Some processes that may be used for further reduction of PFAS concentration are Granular Activated Carbon (GAC), ion exchange, or reverse osmosis. In some embodiments, the ion exchange resin may be regenerable. However, the efficiency of these processes can be affected by the presence of high concentration of ions.

[0297] Even after the acidification step, the oxidation step and the iodine recovery step, there may still high concentrations of ionic species of fluoride and possibly sulfate in the solution. Therefore, in some embodiments, the reduction of concentration of these sulfate and fluoride may be accomplished with addition of an alkaline earth-containing species to the post-treatment solution. These may include some calcium or barium compounds, for example. In some embodiments, such as for economic reasons, the use of calcium compound may be preferred. Suitable calcium compounds include calcium hydroxide and/or calcium oxide. The alkaline earth ion may react with fluoride and sulfate to form minerals like fluorite ( $\text{CaF}_2$ ) and  $\text{CaSO}_4$  (anhydrite) or  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  (gypsum) which may precipitate from the solution. In some embodiments, fluoride may be precipitated, such as by the addition of hydroxyapatite to form fluorapatite. The solids may then be allowed to settle and the supernatant may be further subjected to further processes to remove residual PFASs. Alternatively, in some embodiments, the solids may be removed by electrocoagulation whereby the surface charge of suspended particles is changed and results in the agglomeration and precipitation of the solid matter.

[0298] In some embodiments, unreacted target PFAS molecules could be treated via adsorption processes and reintroduced to the photolysis process.

[0299] After the majority of PFASs are destroyed, some partially fluorinated organic species could still be present. Non-limiting examples of partially fluorinated organic species include the following: fluoroacetic acid, difluoroacetic acid, 2-fluoropropanoic acid, 2,2-difluoropropanoic acid, 1,2-difluoropropanoic acid, 1,1-difluoropropanoic acid, 2,2,2-trifluoropropanoic acid, 1,2,2-trifluoropropanoic acid, 1,1,2-trifluoropropanoic acid, 1,2,2,2-tetrafluoropropanoic acid, 1,1,2,2-tetrafluoropropanoic acid, various isomers of monofluoro-substituted butanoic acid, difluoro-substituted butanoic acid, trifluoro-substituted butanoic acid, tetrafluoro-substituted propanoic acids, pentafluoro-substituted butanoic acids, hexafluoro-substituted butanoic acids and other partially fluoro-substituted pentanoic, hexanoic, heptanoic and octanoic acids. These partially fluorinated organic species contribute to some percentage of the remaining fluorine-containing species measured by total organofluorine analysis. Some of the partially fluorinated species are considered toxic. Therefore, the wastewater may be further treated after photolysis to reduce or remove any remaining partially fluorinated species. In some embodiments, extended UV irradiation

and ARP will reduce the concentration of these species sufficiently, however, this may result in inefficient use of the photochemical reactor. Therefore, post treatment of the reaction mixture is another means to reduce or eliminate these species. In various embodiments, the post treatment may include one or more of various oxidative processes. Potential oxidants that may be used include various organic peroxides (e.g. and inorganic oxides (e.g. peroxide, peroxydisulfate, bleach) and various transition metal oxidants (e.g. permanganate), for example. In some embodiments, these post-treatment reactions can be accelerated by the use of UV irradiation and/or heat.

[0300] The partially fluorinated organic species may be more susceptible to substitution reactions than PFASs. Therefore, various nucleophilic species can be added to destroy some of these species. Nucleophiles containing nitrogen or sulfur can displace fluorine in various embodiments. Some non-limiting examples of sulfur nucleophiles that may be used in various embodiments include hydrogen sulfide and its salts, thiols (RSH), thiolate anions ( $\text{RS}^{\text{sup.}-}$ ), anions of thiolcarboxylic acids ( $\text{RC}(\text{O})\text{—S}^{\text{sup.}-}$ ), where R is an alkyl, aryl, arylalkyl group; and anions of xanthates ( $\text{RO—C}(\text{S})\text{—S}^{\text{sup.}-}$ ) and dithiocarbamates ( $\text{R}^{\text{sub.2N}}\text{—C}(\text{S})\text{—S}^{\text{sup.}-}$ ), where R is an alkyl, aryl, arylalkyl group; and thiosulfate ( $\text{S}^{\text{sub.2O.sub.3.sup.2-}}$ ), for example. Some non-limiting examples of nitrogen containing nucleophiles that may be used in various embodiments include ammonia, amines, hydroxylamine, hydrazine, carbazide, phenylhydrazine, semicarbazide, amide. For example, these may be mixed with the post-treatment solution and the mixture may then be heated, such as in an autoclave.

[0301] The effluent from post-treatment may still contain contaminant species that cannot be discharged into the environment without treatment. Therefore, after photoreduction, the effluent may be collected to test for PFAS. Depending upon the requirements and the amount of remaining PFAS, the effluent may undergo further treatment. For example, additional treatment may be used to remove the leftover contaminant down to the permitted level. For example, in some embodiments, the systems and methods may include additional systems downstream of UV photoreduction systems, such as the use of one or more of Reverse Osmosis (RO), Nanofiltration (NF), Microfiltration (MF), Ultrafiltration (UF), ion exchange resins (IXR), granular activated carbon adsorption (GAC), either individually or a combination. Additionally, these techniques may be utilized in an optimization scenario whereby the destruction process is operated for a shorter time-period and the effluent residuals are concentrated using a post-treatment listed above. Such a configuration would enable shorter residence times and higher throughput in the destruction process while still maintaining process effluent goals.

[0302] The photochemical destruction of PFAS is a sequential process. There are several mechanisms that are thought to be responsible for PFAS destruction. One mechanism is the replacement of fluorine atoms on the PFAS with hydrogen atoms. Another mechanism involves the loss of the carboxylate or sulfonate head groups and subsequent hydrolysis and chain shortening. The resulting new molecules (progeny) also contain fluorine carbon bonds. These progeny molecules can undergo further photochemical destruction. Some of these molecules are also PFAS molecules and, although not necessarily regulated, their removal may be desirable or necessary in the future.

[0303] One measure of the effectiveness of destruction of PFAS molecules and their progeny is the amount of fluoride ion generated. The defluorination percentage deF % can be defined as ratio of fluoride ions generated to the total number of fluorine atoms in the all the PFAS molecule(s). For example, in some photochemical process, the total defluorination levels might be ~70-90%. This means that up to 10-30% of the fluorine is still bound to carbon in such cases.

[0304] A posttreatment to remove these molecules could involve several processes. For example, in some embodiments, persulfate may be used to oxidize the partially defluorinated PFAS molecules, which may result in complete or nearly complete defluorination. For example, the oxidation process described above for pretreatment may also be used for post treatment. Alternatively, or

additionally, in some embodiments, electrochemical oxidation may be used to increase total defluorination levels.

[0305] In some cases, it might be beneficial to reduce the photolysis time, allowing for less time in the photoreactor, and rely on the post treatment defluorination step to achieve high levels of PFAS destruction. For example, the combination of decreased photolysis time in combination with post treatment defluorination may be more efficient and/or may achieve higher levels of PFAS destruction than photolysis alone, which may require extended periods of treatment using a more energy intensive process to achieve the same results.

[0306] Fluoride ion reduction. As discussed previously in this disclosure, the fluoride ion is a product of the photochemical destruction of PFAS. Although some concentration of fluoride ion is acceptable in water, high concentrations of fluoride ion are not desirable. High fluoride concentrations can cause health issues and interfere with the capacity of ion exchange resins or granulated activated carbon beds.

[0307] Lowering the concentration of fluoride ion after the photochemical (such as directly or reductively) decomposition of PFAS can be accomplished by several means. Some effective methods which may be used in various embodiments include reverse osmosis and column adsorption using a material such as a special bone char carbon filter media or activated alumina. The bone char which may be used in various embodiments, also called Brimac, is prepared by cleaning and drying animal bones followed by heating the bones to  $\sim 700^{\circ}\text{C}$ . in the absence of oxygen. The resulting material is porous with a high surface area and is composed of calcium phosphate, calcium carbonate and carbon.

[0308] In various embodiments, fluoride may be removed from the post-treatment solution by precipitation. One example of a precipitation process that may be used in various embodiments includes the following steps: 1) addition of a material that results in the mineralization of the fluoride into fluorite  $\text{CaF}_2$  or fluorapatite  $\text{Ca}_5(\text{PO}_4)_3\text{F}$ , to fluoride containing solution 2) allowing the mineral to settle, and 3) removing the clear solution from the settle solids. Alternatively, the precipitated fluoride mineral may be removed by filtration. In other embodiments, alum may be added to the fluoride containing solution to coagulate fluoride. In this way, the fluorite may be locked up as an insoluble solid mineral. In still other embodiments, magnesium hydroxide can be added to the fluoride solution to absorb the fluoride. The resulting fluorite is non-toxic and may optionally be used in other processes such as to make PFAS.

[0309] In some embodiments, fluoride may be precipitated as fluorite ( $\text{CaF}_2$ ) or fluorapatite  $\text{Ca}_5(\text{PO}_4)_3\text{F}$ . For example, the following materials may be added to the fluoride containing solution to cause precipitations: 1) hydrated lime  $\text{Ca}(\text{OH})_2$ , 2) a combination of water-soluble calcium salts and phosphates to make a hydroxyapatite, 3) hydroxyapatite powder, or 4) bone char powder.

[0310] The fluoride treatments disclosed herein may be used alone or in combination with these or other methods.

[0311] Sulfate precipitation. ARP often uses sulfite. Some of the sulfite is converted to sulfate during the photochemical process. Following photolysis, the remaining sulfite can be converted to sulfate as discussed above. For example, many of the treatments that are used to precipitate fluoride as fluorite may also be used to cause the sulfate to precipitate as gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) in various embodiments. In some embodiments, fluorite and gypsum may be precipitated together. Gypsum can be removed concurrently with fluorite by the same procedures listed above for fluorite or fluorapatite removal. Removing these minerals will reduce the free ion concentration in the solution.

#### Polishing Step

[0312] The effluent from post-treatment may still contain contaminant species that cannot be discharged into the environment without treatment, even after one or more posttreatment steps are applied. The polishing step may act as a final treatment unit that may be useful or needed to

remove any leftover contaminant, such as reducing it to below a desired threshold like a permitted level. Several methods of polishing treatment may be included downstream of one or more post-treatment units and may include processes such as Reverse Osmosis (RO), ion exchange resins (IXR), granular activated carbon beds, and/or membrane filtration. A polishing step may be considered a separate step or may be considered an additional post-treatment step. In some embodiments, polishing may be performed after photolysis and post-treatment steps to bring the levels of one or more components in the wastewater below a limit, such as a regulatory limit required for release of the treated wastewater into the environment.

[0313] An example of a method of PFAS treatment, ending with a post-treatment step followed by a polishing step is shown in the diagram presented as FIG. 28.

[0314] Embodiments of the present disclosure include, but are not limited to the following:

[0315] Various embodiments include ultraviolet photolysis reactors equipped with one or more electrochemical systems capable of reducing photochemical byproducts. For example, in some embodiments, the photoreactor for PFAS destruction includes an ultraviolet light source configured to deliver light at 222 nm and a reactor vessel configured to contain an aqueous solution including PFAS, wherein the light source is positioned to direct light onto the solution contained in the reactor vessel. The light source may be a krypton/chloride excimer lamp. There may optionally be a second or more light sources identical to or different from the first light source, wherein the second light or more light sources are also positioned to direct light onto the contents of the reactor vessel.

[0316] Various embodiments include methods of PFAS destruction including irradiating an aqueous solution comprising PFAS and sulfite with light at 222 nm. The solution may further include a base sufficient to adjust the pH of the aqueous solution to about 10 or more. The solution may further include a halide salt, such as a bromide or iodine salt. The solution may further include a carbonate.

[0317] Various embodiments include photochemical processes and devices that reduce photochemical sensitizer used in UV photolysis byproducts back to the original sensitizer. The sensitizer may be a halogen or pseudohalogen, such as bromide or iodide. The photochemical processes and devices may also include electrochemical elements. For example, combination photochemical and electrochemical devices may include a UV light source and an electrochemical device capable of reducing photochemical byproducts of a sensitizer species back to the original sensitizer.

[0318] Various embodiments include processes for PFAS destruction using an advanced reductive process where the oxidized sensitizer, generated by the interaction of the sensitizer and UV light and ejection of a solvated electron, is reduced back to the sensitizer by an electrochemical process. In some such embodiments, the sensitizer is sulfite and/or iodide. Various embodiments include methods for capturing and/or recycling iodine including adjusting the pH to be between about 3 and about 8 or between about 5 and 7, removing any reducing species that can reduce iodine to iodide, and electrochemically oxidizing the iodide ion to iodine, such as in a module that allows for easy recovery of iodine. Various embodiments include methods, and electrodes for performing the methods, which may include recovering iodine-containing species by electrochemical oxidation of iodide at an electrode including an iodophilic material and an electrically conductive material, such as an electrically conductive polymer, in which the oxidized iodide species is contained within the electrode and optionally also a binder material. The iodophilic material may be starch, chitosan, and/or carboxycellulose, for example, or from cellulose, starch, cationic polymer, polyvinyl alcohol, polyethylene glycol, polypropylene glycol, polyvinylpyrrolidone, polypyrrole, polyaniline, or poly(3,4-ethylenedioxythiophene) a metallocene, a metallocene-containing polymer, and/or a cationic metal complex. In some embodiments, the iodophilic material is a cationic polymer. The conductive material may graphite, graphene, carbon nanotubes, conductive polymers, and/or doped semiconductors and metals, for example. The binder may be polyvinylidene fluoride (PVDF), polyfluoroethylene (PTFE), and/or styrenebutadiene rubber, polyamide. A voltage of 0.3 V vs Ag/AgCl<sub>xx.x</sub> Volts or greater may be applied to the electrode such that iodide is oxidized to iodine

or a polyiodide. The method may optionally further include removing the electrode from the solution and then reducing the iodine/polyiodide containing electrode to release iodide into a solution. The electrode may be bonded to a current collector.

[0319] Various embodiments include methods for recovering and/or capturing and recycling iodide from a photochemical advance reduction process (ARP) solution including 1) adjust the pH of the photochemical ARP solution to between 4 and 8, 2) allow the ARP solution to contact an ion exchange media, 3) remove the ion exchange media from the ARP solution and allow the iodide containing ion exchange media to come in contact with an aqueous salt solution to remove the iodide bound to the ion exchange media. The ion exchange media may be a strong cation exchange media. For example, the ion exchange media may contain a quaternary ammonium group. The aqueous salt solution may be a mixture of water and sodium chloride, sodium bromide, potassium chloride, potassium bromide, sodium hydroxide, potassium hydroxide, sodium sulfate, potassium sulfate.

[0320] Various embodiments include method for capturing iodine including adjusting the pH to be between about 3 and about 8 or between about 5 and about 7, removing reducing species and electrochemically oxidizing the iodide to iodine, such as in a module that allows for recovery of iodine. For example, embodiments include methods for capturing iodine including adjusting the pH to be between about 3 and about 8, or between about 5 and about 7, selective removal of reducing species, such as by addition of an oxidant and electrochemical oxidation of the iodide ion to iodine. In other examples, various embodiments include methods for capturing iodide including adjusting the pH to be between 5 and 7, selective removal of reducing species by addition of an oxidant and either flowing the solution through an ion exchange media to selectively remove the iodide or addition of a tetraalkylammonium salt to precipitate the tetraalkylammonium iodide or both.

[0321] Various embodiments include combination photochemical and electrochemical devices and processes including a UV light source, a boron-doped diamond coated substrate capable of generating solvated electrons upon UV irradiation, and an electrode in close proximity to the diamond coated substrate such that solvated are generated into a high pH region such that the solvated electrons have sufficient lifetimes to react with PFASs and/or other halogenated pollutants. For example, the device for PFAS destruction may include a UV lamp, an electrochemical cell, where a first reducing electrode is a boron-doped diamond which serves as a reducing electrode in a compartment and a second oxidizing electrode is in a separate compartment, the two compartments are separated by ion-exchange membrane. Various embodiments also include processes for PFAS destruction using an advanced reductive process where the source of solvated electron is a boron-doped diamond which serves as the reducing electrode in an electrochemical system whereby hydrogen gas and high pH are generated during the photolysis.

[0322] Other embodiments include photochemical and electrochemical devices including a UV light source and an electrochemical device capable of reducing photochemical byproducts of a sensitizer species back to the original sensitizer and/or capable of reducing an aromatic species to its corresponding radical anion, said radical anion capable of absorbing UV radiation to produce a highly reactive excited state capable of directly reacting with a PFAS or other halogenated pollutant and/or capable of reacting with another molecule to produce a species that can react with a PFAS, such as capable or reacting with carbon dioxide to produce the carbon dioxide radical anion.

[0323] Various embodiments include processes for efficient destruction of PFAS molecules including one or more of following steps: 1) Identification of the major chemical composition of the waste stream, 2) remediation of the waste stream so as to remove chemicals that might interfere with the efficiency of the photochemical process, 3) addition of reagents to the treated waste stream to enable the UV photolytic process including the following materials: i) at least one reagent that can absorb UV photons and upon UV excitation produce chemically active species capable of reacting with one or more PFASs, ii) one or more bases to raise the pH of the solution to greater than 10, iii) optionally, one or more chemicals that can react with UV-produced photolysis product

or convert them back to the original sensitizer or scavenge molecular oxygen, 4) optionally, applying a voltage at a cathode, such that UV-produced products of the sensitizer are reduced back to the original sensitizer, 4) optionally, addition of added base or basic solution to compensate for pH changes caused by the electrochemical or photolytic processes, 5) optionally, purging with an inert gas, 5) optionally, a means to file adequate flow, 6) optionally, the separation of the sensitizer or sensitizer byproducts to be removed from the reaction mixture, 7) optionally, addition of acid to the UV photolyzed mixture to lower the pH to between 4 and 8, 8) optionally, a module for capturing either the sensitizer or reduced products of the sensitizer.

[0324] Various embodiments include UV photochemical reactors including 1) one or more UV sources, 2) one or more electrochemical systems, 3) optionally, one or more systems for dispensing bases or acids to modify the pH of the reaction mixture, 4) optionally, a system for dispensing an inert gas, 5) a device to provide flow, 6) optionally, a module for collecting and or recycling either the sensitizer or reduced form of the sensitizer.

[0325] Other embodiments include processes and devices for PFAS destruction in which 185 nm UV light is used to irradiate an aqueous solution containing PFAS while a voltage is applied to an electrode in proximity to the volume being irradiated such that hydrogen gas is generated in this volume. For example, in some embodiments the device for destroying PFAS includes a 185 nm lamps and an electrochemical device capable of generating hydrogen at one electrode. In some embodiments, following photolysis, the hydrogen is reacted with oxygen. The device optionally also includes a system for removing free fluoride ions after photolysis.

[0326] Various embodiments include photoreactors for PFAS destruction including an ultraviolet light source configured to deliver light at 222 nm and a reactor vessel configured to contain an aqueous solution, wherein the light source is positioned to direct light onto the contents of the reactor vessel. The light source may be a krypton/chloride excimer lamp, for example. The photoreactor of claim 5 further comprising a second or more light sources, identical to or different from the first light source, in which the second or more light sources are also positioned to direct light onto the contents of the reactor vessel. Various embodiments include methods of PFAS destruction including irradiating an aqueous solution comprising PFAS and sulfite with light at 222 nm, such as with the photoreactor described above. The method may include adding a base sufficient to bring the aqueous solution to be treated to a pH of about 10 or more. It may further include addition a halide salt such as bromide or iodine to the aqueous solution to be treated. In some embodiments including bromide, the bromide is present in the aqueous solution at a concentration capable of destroying PFAS at a faster rate than an iodine salt would under the same conditions in which the bromide salt is present at a same or a lower concentration. The aqueous solution may further include carbonate. These devices and methods may be capable of destroying greater than 90%, or greater than 95%, or greater than 99% of the PFAS in the solution.

[0327] Various embodiments include processes for PFAS destruction using an advanced reductive process in which the oxidized sensitizer, such as sulfite or iodide, generated by the interaction of the sensitizer and UV light and ejection of a solvated electron, is reduced back to the sensitizer by an electrochemical process.

[0328] Various embodiments include devices for PFAS destruction including the following: a UV lamp, and an electrochemical cell that can regenerate the sensitizers following photolysis.

[0329] Various embodiments include processes for PFAS destruction using an advanced reductive process where the source of solvated electron is a boron-doped diamond which serves as the reducing electrode in an electrochemical system whereby hydrogen gas and high pH are generated during the photolysis. The source of solvated electron may be a boron-doped diamond which serves as the reducing electrode in an electrochemical system whereby hydrogen gas and high pH are generated during the photolysis. A device which may be used for this process of PFAS destruction may include a UV lamp and an electrochemical cell in which a first reducing electrode is a boron-doped diamond in a compartment and a second oxidizing electrode is in a separate compartment,

the two compartments are separated by ion-exchange membrane.

[0330] Various embodiments include methods of treating wastewater for PFAS reduction including the following steps: a. mixing the wastewater with a persulfate and an acid or a base to increase or decrease the pH; b. subjecting the wastewater including the persulfate and acid or base to an increased temperature and pressure for a period of time sufficient for thermal oxidation; and c. subjecting the thermally oxidized wastewater to photoreduction. The photoreduction may be performed using UV radiation at 222 nm and/or 254 nm. The increased temperature may be about 100 to about 140 degrees Celsius and the increased pressure comprises about 1 bar to about 5 bar, for example. Step b may be performed for about 15 to about 120 minutes, for example. Some embodiments may include further comprising diluting the wastewater after thermal oxidation and prior to photoreduction by about 1 to about 10 fold, or about 2 to about 5 fold. Some embodiments may further include, after step b and before step c, mixing the wastewater from step b with a persulfate a second time and an acid or a base to increase or decrease the pH, and then subjecting the wastewater including the second addition of persulfate and acid or base to an increased temperature and pressure for a period of time sufficient for thermal oxidation.

[0331] Various embodiments include methods of treating wastewater for PFAS reduction including mixing the wastewater with a persulfate and a base to decrease the pH, subjecting the wastewater including the base to ozone treatment at a sufficient rate and for a period of time sufficient for ozone oxidation, and subjecting the ozone oxidized wastewater to photoreduction. The photoreduction may be performed using UV radiation at 222 nm and/or 254 nm, for example.

[0332] Various embodiments include methods of treating wastewater for PFAS reduction including subjecting the wastewater to a pretreatment comprising thermal oxidation or ozone oxidation, mixing the oxidized wastewater with a photosensitizer comprising a sulfite, a halide salt and a base, and subjecting the ozone oxidized wastewater to photoreduction at 222 nm and/or 254 nm. After oxidizing the wastewater and prior to photoreduction, the methods may also include diluting the wastewater 1 to 10 fold, or about 1 to 5 fold.

## EXAMPLES

### Example 1

[0333] Electrochemical Nitrate Reduction. A solution of 500 ppm nitrate (8.06 mM  $\text{NaNO}_3$ ), 0.5 M  $\text{Na}_2\text{SO}_4$ , 20 mM NaOH, 10  $\mu\text{M}$  PFHxS was prepared in DI water. 100 mL were added to both the working electrode chamber and counter electrode chamber of a divided electrochemical cell. A Nafion 212 cation exchange membrane was used to divide the cell. Porous iron was used as the working electrode, platinum mesh was used as the counter electrode, and Ag/AgCl was used as the reference electrode. A flow of argon gas was used to purge the working electrode chamber. A voltage of  $-1.3\text{ V}$  vs Ag/AgCl was applied to the working electrode for 15 hours to reduce the nitrate. The solution collected from the working electrode chamber and an identical nitrate containing solution were both subjected to a photo-reduction process to defluorinate the PFHxS. The defluorination percentage was measured throughout the photo-destruction process and the results are shown in FIG. 29.

[0334] FIG. 29 shows the graph of total percent PFAS defluorination by UV 254 photo-reduction process of 500 ppm Nitrate solutions with and without an electrochemical nitrate reduction pre-treatment. The photo-reduction reaction conditions were 10 mM  $\text{Na}_2\text{SO}_3$ , 2 mM KI. These results demonstrate that photo-reduction is unable to defluorinate PFHxS in the presence of 500 ppm nitrate, with 0% defluorination after 24 hrs. However, an electrochemical reduction of nitrate coupled with photo-reduction was shown to be effective at defluorinating PFHxS, achieving >80% defluorination after 24 hrs.

### Example 2

[0335] Nitrate Nano-filtration. The PFOA degradation kinetics in the membrane reject solution generated from Nano-Filtration (NF) were compared to Reverse Osmosis (RO) in the presence of nitrate ( $\text{NO}_3$ ).

[0336] In the membrane filtration process, 10 L of a synthetic aqueous solution containing 100 ppm of NO<sub>3</sub><sup>-</sup> and ~5 µM of PFOA was transferred into the feed tank of the Benchtop Cross Flow Filtration System (Sterlitech Corporation, Auburn, WA, USA). The benchtop system was equipped with 1812 Element Housing and an RO (SKU: 1180001, TriSep, Vacaville, CA, USA) or NFX (SKU: 1180057, Synder, Vacaville, CA, USA) spiral wound membrane element. The neutral synthetic solution was filtered through the RO or NFX systems at a flow rate of ~2 gal/min and operation pressure of ~250 psi. The membrane permeate was separately collected. 100 mL samples of the membrane reject were collected at the specified concentration factors in both membrane systems. The NO<sub>3</sub><sup>-</sup> concentration in membrane reject was quantified with UV-Vis Absorbance Spectroscopy (UV-2600i, Shimadzu, Kyoto, Japan) using its characteristic 301 nm peak and photoreduction at UV 254 nm.

[0337] For the photoreduction of membrane rejects, 100 mL samples from the RO and NFX membrane reject solutions were transferred into separate 100 mL quartz vials (Q P062, Aireka Scientific Co., Ltd, HK). 0.12604 g (10 mM) of Na<sub>2</sub>SO<sub>3</sub> and 0.332 g (2 mM) of KI were mixed into each 100 mL solution. 0.2 mL (20 mM) of 10 M NaOH was then added to each solution to increase the alkalinity to pH 12. Finally, the solutions were photolyzed in a UV 254 nm photoreactor (LZC-ORG type, Luzchem Research Inc. Canada). This photoreactor is equipped with eight 10-watt UV 254 nm lamps. During photoreduction, 3 mL samples were taken from quartz vials at the specified timepoints for defluorination quantification.

[0338] Defluorination percentage (DeF %) was used to evaluate and compare the destruction performance of the treatment process. During the treatment process, free fluoride (F<sup>-</sup>) concentrations were determined by an ion-selective electrode (ISE, Fisher brand accumet solid-state) connected to a Thermo Scientific Orion Versa Star Pro meter. Then, the defluorination percentage (DeF %) was calculated based on the measured F<sup>-</sup> by the following equation:

$$[00001] \text{DeF}\% = \frac{F_t - F_0}{\text{TOF}}$$

in which F<sub>t</sub> and F<sub>0</sub> are F<sup>-</sup> concentration at time t and initial F<sup>-</sup> concentration, respectively. TOF is the total organic fluorine present. The initial F<sup>-</sup> concentration was 0, and the TOF was calculated based on the initial PFOA concentration and the number of C—F bonds per molecule. A higher DeF % value indicates better efficacy and favorable conversion efficiency of the treatment process in terms of converting organic fluorine into free F<sup>-</sup>.

[0339] The results are shown in the graphs presented in FIGS. 30 and 31. FIG. 30 shows the NO<sub>3</sub><sup>-</sup> concentration (ppm) dependence on the concentration factors of the membrane reject with RO and NFX. The operation condition were aqueous solutions with 100 ppm of NO<sub>3</sub><sup>-</sup> and ~5 µM of PFOA.

[0340] From FIG. 30, it can be seen that NFX was more effective than RO at allowing NO<sub>3</sub><sup>-</sup> to pass through the membrane, leaving less NO<sub>3</sub><sup>-</sup> in the membrane reject. Approximately twice the concentration of NO<sub>3</sub><sup>-</sup> was present in the RO reject compared to the NFX reject. At a concentration factor of 3×, the NO<sub>3</sub><sup>-</sup> concentration in the RO reject solution was 290 ppm, which is higher than that in the NFX reject solution (e.g., 123 ppm).

[0341] FIG. 31 shows a comparison of defluorination percentage (DeF %) from photoreduction of membrane reject from the RO and NFX membranes. The membrane reject was generated from initial aqueous solution with 100 ppm of NO<sub>3</sub><sup>-</sup> and ~5 µM of PFOA with 10 mM Na<sub>2</sub>SO<sub>3</sub>, 2 mM KI, and at pH 12.

[0342] From FIG. 31, it can be seen that the membrane reject from NFX demonstrated superior degradation kinetics than that from RO. After photolyzing for 4 hours, the NFX generated sample demonstrated 40.2% defluorination while the RO generated sample demonstrated only 23.9%. It is believed that this difference is due to the relatively higher concentration of NO<sub>3</sub><sup>-</sup> in the RO sample which scavenges the UV-generated hydrated electrons, reducing their availability and

inhibiting the degradation kinetics.

[0343] RO and NF both demonstrated excellent rejection of long-chain PFAS, but NF rejected less NO.sub.3.sup.-. This is believed to be due to NF having a larger pore size and less electrostatic repulsion than RO. As a result, there is less NO.sub.3.sup.- remaining in the membrane reject to scavenge the hydrated electrons which are essential for promoting the defluorination reaction. While both methods were effective, nano-filtration pretreatment resulted in improved PFOA degradation kinetics compared to reverse osmosis in the presence of nitrate.

### Example 3

[0344] Thermal oxidation pre-treatment. In this Example, as well as Examples 4-8 below, the wastewater used in the experiments was a foam fractionate (FF) from landfill leachate obtained from ALTRA SANEXEN. The PFAS concentrations were measured with the EPA 1633 method on a triple quadrupole mass spectrometer (LCMS-8060, Shimadzu Corporation, USA). The concentrations of all PFAS compounds listed in EPA (Environmental Protection Agency) 1633 method, which included 40 PFAS analytes, were measured.

[0345] About 10 mL of the wastewater was put into a glass pressure vessel and 0.4 g of potassium persulfate and 75 mL of 10 M sodium hydroxide was added. Thermal oxidation reaction conditions were, therefore, 150 mM potassium persulfate and 750 mM NaOH.

[0346] The addition of these reagents resulted in a cloudy solution. The tubes were sealed loosely, to alleviate significant pressure buildup during treatment, and placed in the pressure vessel. The pressure vessel containing the tubes was then heated to and maintained at 120° C. for 120 minutes. After thermal oxidation, the solution was clear and nearly colorless.

[0347] FIG. 32 shows photographs of the raw sample, the sample after settling, the decanted sample after mixing with potassium persulfate and sodium hydroxide, and the sample thermal oxidation. These photos show that the original sample that was very cloudy was clear after thermal oxidation treatment.

[0348] Portions of the thermally oxidized sample were further diluted by a factor of 10, 5, or 2 with deionized water (DI water). The UV transmission spectra of the raw sample and the undiluted and diluted samples after thermal oxidation are shown in FIG. 33 Table 1, below, lists the UV transmittance (%) at 222 nm and 254 nm of the raw wastewater and after thermal oxidation with 0, 2, 5, and 10-fold dilution with DI water.

TABLE-US-00001 TABLE 1 UV Transmittance (%) Wave- After thermal oxidation-dilution at 0, 2, 5, length Raw and 10-fold dilution with DI water (nm) Wastewater 0x 2x 5x 10x 222 0.0 0.0 0.0 0.5 7.6 254 0.0 41.2 65.7 86.6 91.3

[0349] Next, the samples were treated in the photoreactors. Samples of 100 mL of the diluted and undiluted samples were then transferred into 100 mL quartz vials (QP062, Aireka Scientific Co., Ltd, HK). The 100 mL solution was then mixed with 126 mg sodium sulfite (10 mM sodium sulfite), 33 mg potassium iodide (2 mM potassium iodide), and 40-80 mg NaOH (10-20 mM NaOH) as needed to bring the pH to approximately 12. The samples were separately photolyzed in a 254 nm photoreactor and a 222 nm photoreactor. The 254 nm photoreactor (LZC-ORG type, Luzchem Research Inc. Canada) was equipped with eight 10-watt UV 254 lamps. The 222 nm photoreactor was equipped with two 100-watt UV 222 lamps. A detailed description of the 222 nm photoreactor is provided in the applicant's other application U.S. Pat. App. No. 63/591,040 entitled SYSTEMS AND METHODS OF PFAS DESTRUCTION filed Oct. 17, 2023.

[0350] During the photoreaction, 3 mL samples were taken from quartz vials for PFAS quantification at appropriate time intervals. The PFAS concentration was measured with the EPA 1633 method on a triple quadrupole mass spectrometer (LCMS-8060, Shimadzu Corporation, USA). The total PFAS destruction percentage (Destruction %) is calculated based on the sum of PFAS detected in the EPA 1633 method and the results are shown in FIG. 34 FIG. 34 presents graphs of total PFAS destruction percentage by UV 222 and UV 254 photoreduction process at varied dilution factors of the thermal oxidation samples.

[0351] From FIG. 34, UV 222 generally demonstrates better destruction performance than UV 254 for the thermal oxidized samples. For example, for the 2-fold diluted samples, the 2 h total PFAS destruction percentage achieved 53.9% in the UV 222 photoreduction process, while <5% destruction was observed in UV 254 photoreduction after the 2 h reaction. After 8 h reactions, the total PFAS destruction percentage increased to 87.5% in the UV 222 photoreduction process compared to 48.2% in UV 254 photoreduction. The lower dilution degree in the UV 222 photoreduction process is highly beneficial for wastewater treatment applications because it requires less solvent and minimizes waste production, making it more practical for large-scale applications.

[0352] Tables 2a and b and 3a and b below show the concentration of selected representative PFAS during photoreduction at UV 222 and UV 254, respectively, after thermal oxidation treatment of the wastewater samples and dilution by a factor of 2. Thermal oxidation reaction conditions, as described above, were 150 mM potassium persulfate and 750 mM NaOH, maintained at 120° C. for 2 hours. Photo-reduction reaction conditions, as described above, were 10 mM Na.sub.2SO.sub.3, 2 mM KI, pH 12. The results showed that UV 222 and UV 254 photoreduction is generally effective for a wide range of PFAS compounds such as perfluoroalkyl carboxylates and perfluoroalkyl sulfonates. Notably, UV 222 is more effective at the destruction of perfluoroalkyl sulfonates (e.g., PFBS). For instance, for PFBS at an initial concentration of 168-172 µg/L, the remaining PFBS concentration is undetected after 8 h UV 222 photoreduction while there is 152 µg/L PFBS remaining in UV 254 photoreduction.

TABLE-US-00002 TABLE 2a Light PFAS Concentration (µg/L) source Time (h) PFBA PFPeA PFHxA PFHpA PFOA 222 nm 0 70 24 339 47 113 0.5 74 22 308 45 113 1 71 21 287 43 106 2 22 7 60 10 18 4 11 4 13 6 2 6 11 4 7 2 2 8 10 4 7 3 2

Example 4

[0353] Ozone oxidation pretreatment. In this example, the wastewater was pretreated with ozone oxidation. The same wastewater was used as in Example 3. The wastewater was allowed to settle for 12 hours. Then, a nearly clear liquid was decanted. Next, 1.2 g NaOH was added to 300 mL of the decanted liquid. The addition of NaOH resulted in a cloudy solution and the sample was allowed to settle for 12 hours. Then, 200 mL of the solution was treated with 1000 mg/h O.sub.3 for 6 hours using a Portable Ozone Generator, 1000 mg/h Multipurpose Ozone Machine from Shenzhen VANSU Technology Co., Ltd, China. The resulting solution was clear and nearly colorless. Samples of the ozone-oxidized liquid were further diluted by a factor of 10, 5, and 2 with deionized water. The undiluted and diluted samples were analyzed for UV transmission. Photographs of the wastewater before treatment, after settling, after mixing with NaOH, after further setting, and after ozone treatment are shown in FIG. 35.

[0354] The UV transmission spectra of raw wastewater and the diluted samples after ozone oxidation are shown in FIG. 33 and data from these spectra are shown in Table 4, below. Table 4 lists the UV transmittance (%) at 254 nm for raw wastewater and the diluted sample after ozone oxidation.

TABLE-US-00006 TABLE 4 UV Transmittance (%) Wave- After ozone oxidation-dilution at 2, 5, length Raw and 10-fold dilution with DI water (nm) Wastewater 2x 5x 10x 254 0.0 0.1 2.4 14.5

[0355] These results show that ozone oxidation improved the UV transmittance of wastewater. However, the transmittance results from ozone oxidation were lower than that from thermal oxidation.

[0356] Next, the samples were treated in the photoreactors and PFAS levels were measured using the same process as described in Example 3, above. In brief, 100 mL ozone oxidation-dilution samples were mixed with 126 mg sodium sulfite (10 mM sodium sulfite), 33 mg potassium iodide (2 mM potassium iodide), and 40-80 mg NaOH (10-20 mM NaOH) as needed to bring the pH to approximately 12, and photolyzed in either a 254 nm photoreactor or a 222 nm photoreactor. PFAS levels were measured and the total PFAS destruction percentage (Destruction %) results are shown in FIG. 36. FIG. 36 presents graphs of the percentage of total PFAS destruction by the UV 222 and UV 254 photoreduction processes versus time at 10× and 5× dilution factors for the ozone oxidation samples. No graph is shown for the 2× dilution as there was 0% destruction of the PFAS for both the UV 222 and the UV 254 treatments.

[0357] From FIG. 36 it can be seen that, for the ozone oxidation-dilution samples, the UV 222 photoreduction system exhibited better destruction performance than the UV 254 photoreduction system. This is consistent with the results for the thermal oxidized samples in Example 3. In the UV 222 photoreduction system, the total PFAS destruction percentage increased to 61% and 22% for the 10-fold and 5-fold diluted samples, respectively, after an 8-hour reaction. On the contrary, little destruction performance was observed in the UV 254 photoreduction system.

[0358] FIG. 37 presents bar graphs of the PFAS destruction results from Example 1 and Example 2. FIG. 37 shows the total PFAS destruction percentage after 4 hours of treatment in the UV 254 and UV 222 photoreduction system, after either thermal oxidation or ozone oxidation as a pretreatment step. Thermal oxidation was more effective than ozone oxidation in improving the subsequent photoreduction treatment. For the 5-fold diluted sample, thermal oxidation pretreatment improved the 4 h destruction percentage to 85.5% and 91.9% in UV 254 and UV 222, respectively, which is higher than 4.7% and 9.6% in UV 254 and UV 222, respectively, after ozone oxidation as a pretreatment approach.

#### Example 5

[0359] Thermal oxidation pre-treatment. In this example, thermal oxidation of wastewater was performed using varying oxidant (e.g., potassium persulfate) dosages. First, 300 mL of wastewater was mixed with 1.2 g NaOH (3 mL 10 M NaOH solution). The addition of NaOH resulted in a cloudy solution and the samples were allowed to settle for 12 hours. Then, 30 mL of decanted solution was put into individual glass pressure vessels. After that, the 30 mL solution was mixed with varied dosage of potassium persulfate (0.04 g, 0.08 g, 0.2 g, 0.4 g, 0.6 g, 1.2 g) and 10 M sodium hydroxide (0.075 mL, 0.15 mL, 0.375 mL, 0.75 mL, 1.125 mL, 2.25 mL). The pressure vessels were loosely sealed and heated to 120° C. for 120 minutes.

[0360] FIG. 38 shows a photograph of the solutions after thermal oxidation at varied dosages of potassium persulfate and sodium hydroxide. The vessels a-f are shown in order of increasing dosage from lowest dosage (a) to highest (f). The reaction conditions were: a) 5 mM K.sub.2S.sub.2O.sub.8 and 25 mM NaOH; b) 10 mM K.sub.2S.sub.2O.sub.8 and 50 mM NaOH c) 25 mM K.sub.2S.sub.2O.sub.8 and 125 mM NaOH; d) 50 mM K.sub.2S.sub.2O.sub.8 and 250 mM NaOH; e) 75 mM K.sub.2S.sub.2O.sub.8 and 375 mM NaOH and f) 150 mM K.sub.2S.sub.2O.sub.8 and 750 mM NaOH, each maintained at 120° C. for 2 hours.

[0361] As shown in FIG. 38, for the solutions with lower chemical dosages, the solution still looks yellow after thermal oxidation (vessels a-e in FIG. 38). However, at the highest dose, 150 mM K.sub.2S.sub.2O.sub.8 and 750 mM NaOH conditions, the solution after thermal oxidation turned colorless (vessel f in FIG. 38).

#### Example 6

[0362] Thermal oxidation pre-treatment. In this example, thermal oxidation of wastewater was performed under varying pH conditions. About 10 mL of raw wastewater and 0.4 g of potassium

persulfate were added to each of three glass pressure vessels. For the acid reaction conditions, 0.2 mL of 1 M sulfuric acid was added to the sample in the first vessel. For the base reaction conditions, 0.75 mL of 10 M sodium hydroxide solution was added to the sample in the second vessel. For the neutral reaction conditions, no additional chemical was added to the sample in the third vessel. The pressure vessels were loosely sealed and heated to 120° C. for 120 minutes. The resulting solutions were clear and nearly colorless with some sediments in the bottom of the vessels. The clear top layers of each of the oxidized samples were then diluted by a factor of 10, 5, and 2 with deionized water and UV transmittance were measured. Table 5 lists the UV transmittance at 254 nm for the raw sample and the thermal oxidation samples for each condition at 0, 2, 5, and 10-fold dilution with DI water.

TABLE-US-00007 TABLE 5 UV Transmittance (%) at 254 nm Raw Altra After thermal oxidation-dilution at 0, 2, 5, Reaction Waste and 10-fold dilution with DI water condition water 0x 2x 5x 10x Acid 0.0 20.6 46 75.9 86 Neutral 0.0 26.8 52 77.7 88.5 Base 0.0 41.2 65.7 86.6 91.3 (Example 1) Example 7

[0363] Two stage thermal oxidation pre-treatment. In this example, a two-stage thermal oxidation of wastewater was performed and compared the results of different reaction time combinations. First, 300 mL wastewater was mixed with 1.2 g NaOH (3 mL 10 M NaOH solution). The addition of NaOH resulted in a cloudy solution and the sample was allowed to settle for 12 hours. Then, 30 mL of decanted solution was put into each glass pressure vessel and 1.2 g of potassium persulfate and 2.25 mL of 10 M sodium were added. The pressure vessels were loosely sealed and maintained at 120° C. In the first stage thermal oxidation, the reaction time was controlled at 15 to 120 minutes. After the first-stage thermal oxidation, the resulting solutions were clear and nearly colorless. As a second-stage thermal oxidation, another 1.2 g of potassium persulfate was added to the 30 mL solution in the glass pressure vessels and maintained at 120° C. for 30 to 60 minutes. After the second-stage thermal oxidation, the oxidized samples were further diluted by a factor of 10, 5, and 2 with deionized water and UV transmittance were measured. Table 6 lists the UV transmittance at 254 nm for raw, untreated wastewater and the wastewater treated with two-stage thermal oxidation at 0, 2, 5, and 10-fold dilution with DI water.

TABLE-US-00008 TABLE 6 Reaction time combination for the two-stage thermal UV Transmittance (%) at 254 nm oxidation Raw (minutes) Altra After two-stage thermal oxidation-dilution at First stage + Waste 0, 2, 5, and 10-fold dilution with DI water second stage water 0x 2x 5x 10x 15 + 15 0.0 26.7 48.5 75.3 85.2 30 + 30 0.0 42.2 57.5 76.8 88.2 30 + 60 0.0 38.4 64.3 86.9 94.7 60 + 30 0.0 40.6 64.1 86.1 93.8 60 + 60 0.0 39.7 65.5 86.7 93.5 120 + 60 0.0 11.1 54.6 80.9 88.2

[0364] From Table 6, two-stage thermal oxidation significantly improved the UV transmittance at 254 nm compared to the raw wastewater. Thermal oxidation with 120 minutes and then 60 minutes reaction time increased the UV transmittance at 254 nm from 0.0 to 11.1% for the undiluted sample. When reducing the reaction time to 30 minutes and then 30 minutes, the UV transmittance at 254 nm further increased to 42.2%. Compared with 120 minutes and 60 minutes reaction time combination, the reaction time combination of 30 minutes and 30 minutes is beneficial for practical applications due to higher treatment capacity with better improvements in UV transmittance.

### Example 8

[0365] Photosensitizer comparison. In this example, a water sample including PFAS was treated using photoreduction without pretreatment and using two different photosensitizers concentration level. The water sample included TFA (CF.sub.3—COO—) at ~0.9 ppm, PFBA (C.sub.3F.sub.7—COO—) at ~0.6 ppm and 7H-PFHpA (H—C.sub.6F.sub.12—COO—) at 31.8 ppm.

[0366] The first sample of wastewater was mixed with photosensitizer A including 10 mM Na.sub.2SO.sub.3 and 2 mM KI at a pH of 12. The second sample of the same wastewater was mixed with a photosensitizer B including 50 mM Na.sub.2SO.sub.3 and 10 mM KI at a pH of 14.

[0367] Next, the two samples were treated in a 750 mL tube reactor at 254 nm for 24 h and samples

are taken at appropriate time point for analytical purpose such as kinetic fitting of PFAS degradation, defluorination performance calculation in the process.

[0368] PFAS levels were measured before and after photoreduction. Degradation kinetics were calculated based on fitting with pseudo-first-order kinetic model ( $\ln(C_{\text{sub.T}}/C_{\text{sub.0}})=kt$ ), where  $C_{\text{sub.t}}$  and  $C_{\text{sub.0}}$  refers to PFAS concentrations in photoreduction at time T and time 0, respectively.

[0369] A comparison between the degradation kinetics achieved using photosensitizer A as compared to photosensitizer B is shown in the bar graph presented in FIG. 39. FIG. 39 shows the results degradation kinetics for TFA, PFBA, and 7H-PFHpA. In each case, photosensitizer B resulted in surprisingly superior results, with reaction kinetics 4 to 6 times greater than those of this Example.

#### Example 9

[0370] 222 and 254 nm UV photoreduction. The photoreactor used in this example is referred to herein as 222REACTOR1. 222REACTOR1 included two cylindrical lamps, a machined metal support used to support the lamps horizontally at some distance above a level surface, a photoreactor vessel, and a metal enclosure. The cylindrical lamps were krypton/chloride excimer lamps emitting UV radiation at approximately 222 nm. Each lamp was powered by a 20 kilovolt power supply that was located in an enclosure separate from the lamps, and each lamp consumed 100 Watts of electrical power. The lamps were 54 mm in diameter and 460 mm in length. The lamps were statically held 100 mm parallel from each other (center-to-center) at a fixed distance of 57.2 mm (surface to cylinder center) from the horizontal floor of the metal container by a rigid machined aluminum clamp. In other possible embodiments of this photoreactor, lamps of different diameter and length could be used. In other possible embodiments, the machined support for the lamps may be of different dimensions, resulting in the lamps having lesser or greater distances from one another, and lesser or greater distances from the horizontal floor.

[0371] The reactor vessel was a cylindrical quartz vial measuring 40.1 mm in diameter. The total height of the reactor vessel was 114.6 mm, of which 100 mm of the total height was of consistent diameter, the remaining 14 mm tapered to form a threaded top cylinder 12 mm in diameter. In other embodiments, the reactor vessel could have other diameters and or heights.

[0372] The photoreactor was contained in a metal enclosure. A metal filing drawer was used as the metal enclosure. Other structured enclosures such as structured metal enclosures could alternatively be used.

[0373] Seven different PFAS substances were treated in the photoreactor as described below. The tested PFAS included Perfluorobutanoic acid (PFBA), Perfluoropentanoic acid (PFPeA), Perfluorohexanoic acid (PFHxA), Perfluorooctanoic acid (PFOA), Perfluorobutanesulfonic acid (PFBS), Perfluorohexanesulfonic acid (PFHxS) and Perfluorooctanesulfonic acid (PFOS).

[0374] A PFAS stock solution of the seven different PFAS substances was prepared at concentrations between 2.5 and 10 ppm and used in this example. The PFAS stock solution was combined with 25 mM NaHCO<sub>3</sub> and one of various reduction solutions. A control solution which did not contain PFAS was also tested.

[0375] The following five solutions were used as reduction solutions: 1 mM KI and 5 mM Na<sub>2</sub>SO<sub>3</sub>; 1 mM KI and 50 mM Na<sub>2</sub>SO<sub>3</sub>; 10 mM KBr and 50 mM Na<sub>2</sub>SO<sub>3</sub>; 10 mM KI and 50 mM Na<sub>2</sub>SO<sub>3</sub>; 50 mM Na<sub>2</sub>SO<sub>3</sub>. A sixth solution was also used which included only reagent water (for direct irradiation).

[0376] The solutions were separately added to the reactor vessel and a threaded plastic cap with a silicon septum was screwed to the top of the vial to create a leak proof seal. The reactor vessel was placed between the parallel Krypton/Chloride lamps in the 222 Reactor 1, allowing for radiation to enter the vessel from two sides. The solutions were each irradiated in the photoreactor at 222 nm for three hours. The temperature of the reactor ranged between 55 and 60 degrees Celsius during the reaction.

[0377] The amount of PFAS present in the solutions was measured periodically during the photoreactor treatment by stopping the reactor, withdrawing samples of the reactor solution and pipetting them into vials to preserve them for LCM S analysis.

[0378] The results of the photoreaction treatment for each PFAS in each solution are shown in the graphs presented in FIGS. **40** and **41**.

[0379] FIG. **40** shows the concentration of the PFAS as a function of time for the photoreduction of PFAS in each reduction solution at 222 nm. Qualitative inspection of FIG. **1** shows that the rates of PFAS destruction are faster in solution containing iodide/sulfite compared to the rate of PFAS destruction under direct irradiation in pure water. It is also evident that the rate of PFAS concentration loss in the model solution, 1 mM KI and 5 mM KI, is faster than any other solution.

[0380] FIG. **41** shows the percent PFAS destruction as a function of time for the photoreduction of PFAS in each reduction solution at 222 nm. In both of these figures, the reduction solution which was used is indicated in the header. FIG. **2** demonstrates that there is a quantitative increase in PFAS destruction within a 3-hour period when the model solution is compared to all other solutions and reagent water. Additionally, it is evident that in the model solution, the percentage of both carboxylated and sulfonated PFAS destruction is greater than other solutions, and much greater than that in the case of direct irradiation in reagent water.

[0381] FIG. **41** also includes data for the PFAS substances that were prepared as treatment solutions and treated as described in example 1 above, using the 10 mM KI and 50 mM Na.sub.2SO.sub.3 reduction solution. However, these solutions were irradiated at 254 nm in a separate photoreactor referred to herein as the 254REACTOR. The 254REACTOR was a LUZCHEM L2C-ORG box reactor equipped with 10 8-watt low pressure mercury lamps. The treatment solution was irradiated in the 254REACTOR for three hours. These results are shown in column 5 of FIG. **41**.

[0382] Select experiments were repeated three times and their three independent experimental results were averaged and plotted with statistical analysis. The results are shown in FIG. **42**. The results are contrasted with those for direct irradiation of the PFAS solution at 222 nm. Inspection of FIG. **3** reveals that in the n=3 replicate trial, the percent destruction and decrease in concentration over time of the individual PFAS compounds are statistically distinguishable in the model solution. For example, the percentage destruction of the carboxylated derivatives over time is, to 68% confidence, greater than that of PFHxS and PFOS, which is greater than PFBS. This difference is more acutely manifested in the case of the solution in which bicarbonate is not present. Within the confidence limits, destruction in the 1 mM KI/5 mM Na.sub.2SO.sub.3 solution is also much greater than that which occurs by direct irradiation in reagent water.

[0383] The data from this example was normalized and fit to a single exponential function,

[00002] 
$$C(t) = C_o e^{-\frac{t}{\tau}} \quad (1)$$

where C(t) is the concentration at time t, C<sub>o</sub> is the initial concentration, and the first order time constant (the inverse of the rate constant). The first order rate constants were translated to half-lives (multiplication by 0.6901). Data plotted from FIG. **2** was fit into Eqn. 1. Exemplary fits are shown in FIG. **4** for time dependent PAS destruction using a solution of 1 mM K, 5 mM Na.sub.2S.sub.3 and 25 mM NaHCO.sub.3 solution. A smaller time constant indicates less time is required to destroy the PEAS.

[0384] Table 7, below, shows Equation 1 fit to data for time dependent PEAS destruction using 1 mM KI, 5 mM Na.sub.2SO.sub.3 and bicarbonate solution. The first order time constants,  $\tau$ , was determined from the data plotted in columns 1,3,4,5 and 6 and were translated into half-lives in Table 7. Table 7 shows the time constants for PEAS destruction versus time using a 222 nm light source for several solutions and reagent water. t<sub>sup.1/2</sub> is the first order time constant,  $\sigma$  is the error in t<sub>sup.1/2</sub> at a confidence limit of 68%. The dashes for PEBS, PEHxS and PEGS in Reagent Water Column indicate correspond to very high t<sub>sup.1/2</sub> values.

TABLE-US-00009 TABLE 7 PFAS Destruction:  $\lambda = 222$  nm,  $n = 1$ , nominal 5 ppm PFAS 1mM KI 10 mM KI 10 mM KBr, Reagent 5 mM Na.sub.2SO.sub.3 50 mM Na.sub.2SO.sub.3 50 mM Na.sub.2SO.sub.3 50 mM Na.sub.2SO.sub.3 Water t.sup.1/2,  $\sigma$ , t.sup.1/2,  $\sigma$ , t.sup.1/2,  $\sigma$ , t.sup.1/2,  $\sigma$ , min min min min min min min min min min min min PFBA 18.0 0.62 40.5 2.1 28.8 4.0 32.8 1.6 93.5 15 PFPeA 16.0 0.41 35.5 1.8 27.5 3.4 29.6 1.1 48.5 4.7 PFHxA 16.6 0.55 41.9 3.4 29.8 3.7 31.5 1.3 40.4 1.5 PFOA 16.7 0.76 8.0 2.3 40.9 9.0 32.2 1.0 33.2 1.5 PFBS 194 43.6 364 66 266 327 443 103 — PFHxS 51.3 8.2 84.5 8.3 65.1 18.7 85.2 8.3 — PFOS 33.7 9.1 60.4 22 65.1 16.6 57.5 11.0 — All solutions contained ~5 mM PFAS;  $\sigma$  is the calculated 68.3% confidence interval; — indicates data too noisy to fit (error bars larger  $\tau$ )

[0385] The half-life data plotted in FIG. 42 are shown in Table 8. Table 8 shows a comparison of the time constants for PEAS destruction versus time using a 222 nm light source for the  $n=1$  and  $n=4$  experiments using a solution of 1 mM KI and 5 mM Na.sub.2SO.sub.3. The half-life, t.sup.1/2, is the half-life for PFAS destruction,  $\sigma$  is the error in t.sup.1/2 at a confidence limit of 68%.

TABLE-US-00010 TABLE 8 PFAS Destruction: 1 mM KI, 5 mM Na2SO3,  $\lambda = 222$  nm, nominal ppm PFAS  $n = 1$   $n = 4$  Compound t.sup.1/2, min  $\sigma$ , min t.sup.1/2, min  $\sigma$ , min PFBA 18.0 0.62 21.2 0.82 PFPeA 16.0 0.41 19.7 0.97 PFHxA 16.6 0.55 22.2 1.2 PFOA 16.7 0.76 20.9 0.97 PFBS 194 43.6 211 23.2 PFHxS 51.3 8.2 60.4 9.2 PFOS 33.7 9.1 41.7 7.0 All solutions contained ~5 mM PFAS;  $\sigma$  is the calculated 68.3% confidence interval; — indicates data too noisy to fit (error bars larger  $\tau$ )

[0386] The results of these exemplary fits shown in FIG. 43, and those for all of the  $n=1$  solutions, are presented in Table 7. FIG. 43 shows Eqn. 1 fit to the data for time dependent PEAS destruction using 1 mM KI, 5 mM Na.sub.2SO.sub.3 and bicarbonate solution. Within the confidence limits, the rate of the model solution is distinguishable from the other solutions and reagent water.

#### Example 11

[0387] 222 nm photoreduction. A different 222 nm photoreactor design was used in this example. This photoreactor, referred to herein as 222REACTOR2, included a photoreactor vessel, a clamp, a lamp, a transparent sleeve, a pump and various valves and tubing.

[0388] The photoreactor vessel was a non-porous cylinder sealed on one end to contain a liquid. The bulb of the lamp was also cylindrical, with a diameter less than that of the photoreactor vessel cylinder. The cylindrical lamp bulb was placed into the cylinder (within the transparent sleeve) and secured such that the long axis of the bulb was parallel to the long axis of the cylinder and centered in the photoreactor vessel cylinder. The photoreactor vessel cylinder included a flow regulated outlet in close proximity to the base of the cylinder through which liquid to be drained. The photoreactor vessel cylinder also included an inlet in proximity to the top of the cylinder through which liquid was added the cylinder. A clamp held photoreactor vessel cylinder with the long axis of the cylinder vertically oriented at a right angle to a horizontal table top.

[0389] The photoreactor vessel cylinder was about 75 mm in diameter and 500 mm in length and was made of stainless steel with walls about 3 mm thick. The inlet and outlet of the photoreactor vessel cylinder were machine threaded openings capable of accepting connections to flexible or rigid tubing. In this particular arrangement the machine threaded openings were stainless steel, 1/2 inch National Pipe Thread fittings, welded, brazed or soldered to the face of the metal cylinder.

[0390] The cylindrical lamp bulb was inserted into a transparent sleeve that was centered on the top face of the photoreactor vessel cylinder, and parallel to the long axis of the photoreactor vessel cylinder. A stainless steel cap held and secured the sleeve. The cap included a centered hole through which the sleeve was inserted, and an outer cylindrical ring with interior diameter (I.D) slightly greater than the outer diameter of the stainless steel cylinder. The cap was a welded and machined stainless steel cylinder about 70 mm in length and 100 mm in diameter. The transparent sleeve was about 500 mm in length and about 55 mm (OD) in diameter and was sealed on the bottom end to prevent liquid from contacting the lamp. The transparent sleeve was made of quartz capable of

transmitting light at and below wavelengths of about 225 nm.

[0391] The lamp was a krypton/chloride excimer that consumed 100 Watts of power and was powered by an external 20 kV power supply. The lamp bulb measured about 54.6 mm in diameter and 460 mm in length and produced radiation of about 222 nm, with a full-width-half-max of about 4 nm.

[0392] The 222 REACTOR2 also included a pump that was connected in-line with rigid stainless steel tubing between the outlet and inlet of the photoreactor vessel. A series of valves were located in-line with the tubing on the suction side of the pump to stop the flow of liquid from the base of the reactor vessel and divert the pump suction to a container from which liquid can be drawn into the reactor. A series of valves were also located in line with the pressure side of the pump to stop the flow of liquid from the pump and divert the flow of the pump to an exterior container from which fluid could be collected from the reactor. The pump was a low flow circulating pump of the type often used in passive or active solar heating applications. The tubing was comprised of  $\frac{1}{8}$  inch OD stainless steel tubing that was bent to form a sealed matrix of connections between the valves and pump and the metal cylinder of the photoreactor.

[0393] A comparison was made between using Na<sub>2</sub>SO<sub>3</sub> alone versus Na<sub>2</sub>SO<sub>3</sub> and KBr. Each treatment solution included 10 ppm PFOA and either 5 mM Na<sub>2</sub>SO<sub>3</sub> alone or 5 mM Na<sub>2</sub>SO<sub>3</sub> and 150 mM KBr. No NaHCO<sub>3</sub> was included in either treatment solution, though pH 12 was attained through addition of sodium hydroxide.

[0394] The reactor solutions were separately placed into the photoreactor vessel and irradiated at 222 nm in the 222REACTOR2 for 24 hours.

[0395] The amount of PFOA present in the solutions was measured periodically during the photoreactor treatment by withdrawing samples from the outlet of the photoreactor vessel and preserving them for LC-MS analysis. The results for the first four hours are shown in FIGS. 44 and 6.

[0396] FIG. 44 shows the time dependent destruction of PFAS upon photolysis of PFOA using 5 mM Na<sub>2</sub>SO<sub>3</sub> and 150 mM KBr (blue squares) and data for time dependent defluorination of PFOA using ONLY 5 mM Na<sub>2</sub>SO<sub>3</sub> (red triangles). The data is represented by the symbols, and best exponential fit is shown by the lines.

[0397] FIG. 45 shows the time dependence of fluoride ion (F<sup>-</sup>) concentration resulting from the defluorination of PFOA. The blue squares show the fluoride ion concentration (symbols) versus time using 5 mM Na<sub>2</sub>SO<sub>3</sub> and 150 mM KBR, with the blue line showing the best exponential fit. The red triangles show the fluoride ion concentration versus time using only 5 mM Na<sub>2</sub>SO<sub>3</sub>, with the red line showing the best exponential fit.

[0398] These results show that the reactor solution which included bromide resulted in more rapid and more complete defluorination than the reactor solution which included only Na<sub>2</sub>SO<sub>3</sub>.

[0399] It is worth noting that in Example 10, there was basically no statistical difference between the rate of decay in the 10 mM KBr/50 mM Na<sub>2</sub>SO<sub>3</sub> solution when compared to the solution 50 mM Na<sub>2</sub>SO<sub>3</sub> solution without KBr. However, in Example 10, which included higher levels of KBr (and lower levels of sulfite), the inclusion of KBr had a definite positive result of PFOA destruction.

[0400] Given that the molar absorptivity of sulfite is 70 times greater than that of KBr at 222 nm (5400 M<sup>-1</sup>cm<sup>-1</sup> for sulfite [in house experiment], compared to 77.61 M<sup>-1</sup>cm<sup>-1</sup> for KBr [Birkmann et al, Water Practice and Technology (2018) 13(4); 879-892]), it is believed that the sulfite was absorbing most of the light in Example 1. In contrast, when the sulfite was reduced and the bromide increased in Example 2, the KBr was effective at improving PFOA destruction. Though we do not know the relative quantum efficiency for photogenerated electrons at this wavelength, assuming that this yield is comparable in KBr and KI, then increasing the concentration of KBr 147 times ( $\epsilon=11,527$  M<sup>-1</sup> cm<sup>-1</sup> for KI, compared to 77.61 M<sup>-1</sup>cm<sup>-1</sup> for KBr [Birkmann et al, Water Practice and Technology (2018) 13(4); 879-892])

relative to that of KI may yield comparable effects.  $F$  is the molar extinction coefficient.

[0401] Similarly in Example 10, it was not discernible that the rates of PFAS destruction were significantly different when comparing a solution of 10 mM KI/50 mM Na.sub.2SO.sub.3 solution to the 50 mM Na.sub.2SO.sub.3 solution. In fact, arguably the rates could be slightly less with the addition of KI. Thus, it would make sense to study in more detail the rate of PFAS destruction on the concentration of a solution containing only Na.sub.2SO.sub.3. A direct comparison of the rate of destruction between a 5 mM solution of Na.sub.2SO.sub.3 and that of the model solution should give clear indication if the 1 mM KI matters at all at this concentration. Additionally, it has been calculated that for light to penetrate at least 1 cm into the reactor cell at 222 nm, concentrations of KI and Na.sub.2SO.sub.3 up to three orders of magnitude less than the model solution are necessary. Recognizing the important inverse relationship between light penetration and concentration of detached electrons in solution necessary for PFAS destruction, concentrations of KI, Br and Na.sub.2SO.sub.3 in the tens to hundreds of  $\mu$ M regime may have an effect on the effect on the rate of PFAS destruction.

#### Example 12

[0402] 222 and 254 UV photoreduction. Further experiments were performed to evaluate the destruction of PFAS foam fractionate using 222 nm and 254 nm UV radiation.

[0403] Foam fractionate water was obtained from the Minnesota Pollution Control Agency (MPCA). The primary compounds in the MPCA sample were determined to be PFOA and PFOS. Other compounds (PFHxA, PFHxS, PFHpS) were detected, though at concentrations below the limit of quantitation. Due to a 5-fold dilution of the samples for LC-MS analysis, the limit of quantitation (LOQ) for the analysis was back-calculated as  $\sim$ 10 ppb for each compound in the fractionate sample.

[0404] The 222REACTOR1 was used to deliver 222 nm radiation. The reagents used with the 222 nm radiation included 1 mM potassium iodide (KI) and 5 mM sodium sulfite (Na.sub.2SO.sub.3). The 5 $\times$  diluted samples were placed in the 222 Reactor 1 and irradiated for 5 hours under UV irradiation at 222 nm.

[0405] The 254REACTOR was used to deliver 254 nm radiation. The reactor solution used with the 254 nm radiation included 40 mM potassium iodide (KI) and 200 mM sodium sulfite (Na.sub.2SO.sub.3). The 5 $\times$  diluted samples were placed in the 254 Reactor and irradiated for 6 hours under UV irradiation at 254 nm.

[0406] For each reactor, the amount of PFAS present in the solutions was measured periodically during the photoreactor treatment by stopping the reactor, withdrawing samples from the reactor vessel and pipetting them into vials to preserve them for LC-MS analysis.

[0407] The results are shown in FIG. 46, which shows the percentage of PFAS destruction over time (top row) and the PFAS concentration over time (bottom row) for both the 222 nm (left) and 254 nm treatments. The 5 $\times$  dilution samples reached a thorough extent of destruction by 5 hours under UV at 222 nm, and by 6 hours under UV 254 nm ( $\sim$ 99%). Other compounds (PFHxA, PFHxS, PFHpS) showed concentrations below the limit of quantitation at this timepoint as well.

[0408] The results demonstrate that PFAS destruction is similar between the two experiments. However, the treatment at 222 nm achieved these results using a significantly lower iodide and sulfite concentrations (1/40th) than the 254 nm treatment. This is particularly important with regards to iodine due its greatly elevated cost as compared to the rest of the reagents. Equivalent or greater destructive performance in the 222 nm system at conditions with significantly reduced concentrations of iodide—and thus a commensurate decrease in cost—therefore represents a significant advancement towards developing an effective and economical means of PFAS destruction. This cost savings would be particularly important in large-scale processes, in terms of efficiency and operational cost savings.

#### Example 13

[0409] The following photoreactor and experimental design were used in Examples 13 and 14, and

15. The photoreactor included the following: a Pyrex cylindrical beaker (84 mm in diameter, 124 mm in height, 600 ml total capacity); a rubber stopper with tapered sides, diameter at half height of 84 mm; two quartz sleeves that are sealed on one end, 23 mm in diameter, 190 mm in length (Technical Glass, GE 214); and two 15 Watt ultraviolet bulbs. Two distinctly different types of ultraviolet bulbs, interchangeable in the reactor, were used depending upon the experiment: 1) UV 222 nm excimer bulbs, 23 mm in diameter, 190 mm in length; and 2) UV 185/254 nm bulbs, 19 mm in diameter, 200 mm in length.

[0410] The rubber stopper had two 23 mm diameter holes cut along the diameter with the centers of these holes 16 mm from the center of the rubber stopper, as well as 4 smaller holes (2×6.3 mm and 2×7.6 mm) placed in a 60 mm square pattern with the center of this square coincident with the center of the stopper. When a salt bridge was used, an additional 1 cm hole was present in the stopper to accommodate it. The quartz sleeves fit into the 23 mm holes and protruded through the stopper such that the sealed end of the sleeve protruded 75 mm beyond the lower flat face of the tapered plug. The rubber stopper fit snugly into the beaker such that the quartz sleeves protruded into the beaker. The UV bulbs were placed into the quartz sleeves through the open (top end) of these sleeves that protrude into the beaker. The beaker (with stir bar) was placed onto a stir plate. The smaller diameter holes present in the reactor are ports for probes, electrodes and sparging lines in experiments described below.

[0411] Photo-destruction was performed by decanting 450 ml of sample PFAS solution into the 600 ml beaker. The solution was sparged with argon for 15 minutes, stirred and then the lamps turned on (time zero). Samples are drawn at regular time intervals throughout the photo-destruction process. These samples are analyzed with a fluoride sensor to detect free-fluoride ion release from the destruction of the PFOS.

[0412] Electrochemical reduction of iodine. In this example, recycling of the iodide was tested using no sulfite by electrochemical reduction of the photochemically produced iodine radical.

[0413] A 450 ml solution containing 5 ppm Perfluorooctane Sulfonic Acid (PFOS), 1 mM potassium iodide (KI), 0.1 M sodium sulfate, and 20 mM sodium hydroxide (NaOH) was decanted into the reactor. One end of a (1 M KCl) salt bridge was inserted through the stopper and into the reactor solution. The other end of the salt bridge was placed into a stirred 1 M aqueous KCl solution that contained a 2×2 cm platinum mesh counter electrode that served as an anode throughout the experiment. A 2×2 cm platinum mesh working electrode and a Ag/AgCl reference electrode were suspended in the reactor cell solution. A potential of -0.7 V vs Ag/AgCl was applied to the working electrode using a potentiostat (BioLogic). The platinum working electrode served as a cathode and reduced the oxidized iodine radical back to iodide. The solution was sparged with argon prior to and during the PFOS destruction experiment. The working electrode was located approximately 2 cm from the quartz sleeve housing the lamp. Time zero for the PFOS destruction experiment was when the lamps were turned on. In this experiment, UV 222 nm bulbs were used. The transmission of the quartz sleeves at 222 nm was 0.8. Samples were drawn through an access port in the rubber stopper at regular time intervals, with a +/-30 second sampling error.

[0414] The results are shown in the graph presented in FIG. 47. FIG. 47 is a graph of percent of free-fluoride relative to the theoretical maximum as a function of time for the destruction of 5 ppm PFOS as described above. The percent of free-fluoride is for a solution in which a -0.7 V vs Ag/AgCl potential was applied to the electrodes (black squares). No potential was applied across the electrodes (grey circles) for the control. Error bars are drawn at a confidence level of 95%. After 120 min the control experiment with no potential applied achieved only 3% defluorination, meanwhile, the electrochemical experiment achieved 18% defluorination after 120 min. This demonstrates the ability of an electrochemical system to regenerate iodide during a photoreduction experiment, achieving effective PFAS destruction with no or minimal sulfite.

#### Example 14

[0415] Perfluoro-octane sulfonic acid (PFOS) destruction using electrochemical generation of

hydrogen. In this example, a 185 nm light was used to generate hydroxyl radicals. These hydroxyl radicals react with electrochemically generated molecular hydrogen to ultimately form solvated electrons used in the reductive destruction of PFAS. Three experiments are shown here as part of this example: 14 (a) a control destruction experiment in which a reactor solution of PFOS, sodium sulfate, and sodium hydroxide was run with the 185 nm radiation but without voltage applied to the electrodes; 14 (b) a destruction experiment in which a reactor solution of PFOS, sodium sulfate, and sodium hydroxide was run with 185 nm radiation with both anode and cathode present in the reactor cell; and 14 (c) a destruction experiment in which a reactor solution of PFOS, sodium sulfate, and sodium hydroxide was run with 185 nm radiation with the cathode in the reactor cell, and the anode isolated in a separate cell. The anode cell and cathode cell were connected with a salt bridge.

[0416] In examples 14 (a)-14(c), the starting point of the PFOS destruction experiment (time zero) was the time-point at which the lamps were turned on. The reactor solutions were sparged with argon during the experiment. Sparging began 15 minutes prior to the start of the experiments. The reactor solutions were stirred constantly throughout the course of the experiment. In this experiment UV 185/254 nm bulbs were used. The transmission of the quartz sleeves at 185 nm was 0.63. Samples were drawn through an access port in the rubber stopper at regular time intervals, with a  $\pm 30$  second sampling error.

[0417] Example 14 (a): A 450 ml solution containing 0.1 M sodium sulfate, 20 mM sodium hydroxide and 5 ppm PFOS was stirred and decanted into the photoreactor. This experiment served as a control. No voltage was applied to the cell. The UV lights were turned on in the photo-reactor during this experiment.

[0418] Example 14 (b): A 450 ml solution containing 5 ppm PFOS, 1 mM sodium hydroxide and 5 mM sodium sulfate (electrolyte) was decanted into the photoreactor. A working electrode and counter electrode (both 10×10 cm platinum coated Ti mesh electrodes squares, bent to conform to the diameter of the reactor beaker) and a reference electrode (Ag/AgCl) were suspended in the reactor cell solution. A potential of  $-1.1$  V vs Ag/AgCl was applied to the working electrode, which served as the cathode. This applied potential was above that needed to electrolyze the water into molecular hydrogen at the cathode and molecular oxygen at the anode. The electrodes were located approximately 2 cm from the reactor quartz sleeves housing the lamps.

[0419] Example 14 (c): A 450 ml solution containing 5 ppm PFOS, 1 mM sodium hydroxide and 5 mM sodium sulfate was decanted into the photoreactor. A working electrode (10×10 cm platinum coated Ti mesh electrode square, bent to conform to the diameter of the reactor beaker) was suspended in the photoreactor solution. One end of a (1 M sodium sulfate) salt bridge was inserted through the stopper and into the reactor solution. The other end of the salt bridge was placed into a beaker of stirred 1 M aqueous sodium sulfite solution in which a platinum mesh counter electrode, identical to the working electrode, was suspended. This electrode served as an anode throughout the experiment. The counter electrode oxidized sulfite to sulfate at the electrode interface. The salt bridge insured that charge neutrality was maintained between the anode and cathode cell. The working electrode was located approximately 2 cm from the reactor quartz sleeves housing the lamps. During the destruction experiment, a voltage of 58.13 Volts was applied across the electrodes, leading to a current between the electrodes of 49 mA at the beginning of the experiment and 86 mA by the end of the experiment 2 hours later. After 5 minutes of passing the initial current, visible hydrogen bubbles could be seen forming on the platinum mesh electrode.

[0420] The results of example 14 are shown in the plot presented in FIG. 48. This figure is a plot of the percent of free-fluoride evolved relative to the theoretical maximum as a function of time for the destruction of 5 ppm PFOS as described for examples 14 (a)-14(c). Error bars are drawn at a confidence level of 95%. The result of example 14 (a), the control experiment, is plotted with gray circles. After 120 min this control experiment achieved only ~10% de-fluorination. The result of example 14 (b) is plotted with gray squares; here both the anode and cathode were present in the

photoreactor. In this experiment essentially zero defluorination was achieved after 2 hours. This may have been due to the oxygen that was present in the reactor cell due to water photolysis. Oxygen is a strong quencher of solvated electrons. The result of example 14 (c) is plotted with black squares. In this experiment the anode and cathode were present in different cells connected by a salt bridge. A 35% de-fluorination after 120 min was achieved in this experiment. This experiment demonstrates that effective PFOS destruction can be achieved without the addition of chemical photosensitizers by utilizing in-situ electrochemical hydrogen generation.

#### Example 15

[0421] Iodide recovery electrode synthesis. An iodide recovery electrode was synthesized by mixing 2 g starch and 2 g graphite with a mortar and pestle. The mixed powders are then placed in a ball mill that was run at 1200 rpm for 60 minutes. The resulting powder was then mixed with 5 mL of a 60% PTFE solution with a mortar and pestle. The result was a flexible putty like material that was repeatedly folded over on itself to create homogeneity and structural integrity. The material was then dried in an oven at 80° C. for 6 hours to remove water from the structure. The result was a firm but flexible sheet. A 2×2 cm square was cut out of the sheet and a conductive carbon paint was used to attach the sheet to a conductive carbon paper current collector. The carbon paper was then masked with Teflon tape and lacquer so that only the iodide recovery material was exposed to solution during operation.

#### Example 16

[0422] Iodide recovery using electrode. A 0.1 M Na<sub>3</sub>PO<sub>4</sub> pH 7 solution was prepared for use in a 3-electrode cell in which the working electrode was the iodide recovery electrode described in example 14, the counter electrode was Pt mesh, and the reference electrode was Ag/AgCl. An oxidative linear sweep voltammetry (LSV) was performed as seen in graph a of FIG. 49, and a reductive LSV was performed as seen in graph b of FIG. 49.

[0423] Potassium iodide was then added to the solution to bring it to 50 mM KI. The same oxidative LSV was performed as seen in graph a. The significantly higher current generated in the 50 mM KI solution is indicative of iodide oxidation occurring. A galvanostatic electrolysis was then performed at 0.25 mA/cm<sup>2</sup>. After 40 minutes a yellow color was observed in the solution near the working electrode, indicating that the electrode was fully saturated with I<sub>3</sub><sup>-</sup>. A fresh 0.1 M Na<sub>3</sub>PO<sub>4</sub> pH 7 solution was then prepared and the same reductive LSV was performed as seen in graph b.

[0424] In the results shown in graph a, the oxidative LSV of the iodide recovery electrode in 0.1 M Na<sub>3</sub>PO<sub>4</sub> pH 7 is shown without iodide (solid) and with 50 mM KI (dashed). In graph b, the reductive LSV of the iodide recovery electrode is shown in 0.1 M Na<sub>3</sub>PO<sub>4</sub> pH 7 (solid) and after loading with I<sub>3</sub><sup>-</sup> (dashed). The much higher current with the peak centered at -1.1 V vs Ag/AgCl can be attributed to reduction of the I<sub>3</sub><sup>-</sup> that had been immobilized in the electrode. A galvanostatic electrolysis was then performed at -0.25 mA/cm<sup>2</sup> for 40 minutes convert the I<sub>3</sub><sup>-</sup> to I<sup>-</sup> and release it into solution. The resulting solution contained 0.44 mM iodide.

#### Example 17

[0425] Iodide recovery using electrode. Four cycles of iodide capture and discharge were performed using the iodide recovery electrode described of example 14. The iodide capture media was 100 mL of 0.1 M Na<sub>3</sub>PO<sub>4</sub> 2 mM KI pH 7 solution. For iodide capture, 3-electrode undivided cell was used in which the working electrode was the iodide recovery electrode described in example 13, the counter electrode was Pt mesh, and the reference electrode was Ag/AgCl. The iodide capture step was performed with a galvanostatic electrolysis at 0.25 mA/cm<sup>2</sup> for 30 minutes. After each iodide capture step, the electrodes were thoroughly rinsed with DI water, dried, and set up for the iodide recovery step. The iodide recovery media was 100 mL of 0.1 M Na<sub>3</sub>PO<sub>4</sub> pH 7 solution. For iodide recovery 3-electrode cell divided with a Nafion 212 cation exchange membrane was used in which the working electrode was the iodide

recovery electrode described in example 13, the counter electrode was Pt mesh, and the reference electrode was Ag/AgCl. The iodide recovery step was performed with a galvanostatic electrolysis at  $-0.25\text{ mA/cm}^2$  for 30 minutes. After each iodide recovery step, the electrodes were thoroughly rinsed with DI water, dried, and set up for the iodide capture step.

[0426] The removal and recovery of iodide after the 2<sup>nd</sup> and 4<sup>th</sup> cycle are shown in FIG. 50, which shows total iodide removed (circle) and recovered (square) from the 0.1 M Na<sub>2</sub>SO<sub>4</sub> 2 mM KI pH 7 solution after 2 and 4 cycles of iodide capture and discharge. After 2 cycles 5.5% of the initial iodide had been removed from iodide capture solution and 2.9% of the initial iodide had been recovered into the recovery solution for an efficiency of 53%. After 4 cycles a total of 10.3% of the initial iodide had been removed from the iodide capture solution and 5.4% of the initial iodide had been recovered into the iodide recovery solution for an efficiency of 53%.

#### Example 18

[0427] Iodide recovery using anion exchange resin. A solution of 2 mM KI 10 mM Na<sub>2</sub>SO<sub>4</sub> was prepared using DI water. 300 mL of solution and 0.5 g of commercially available AmberSep anion exchange resin in the form of beads about 2 mm in diameter were placed in a bottle. 300 mL of solution and 0.5 g of commercially available AmberLite anion exchange resin in the form of beads about 2 mm in diameter were placed in a different bottle. Both bottles were shaken for 24 hours to mix the solutions and resins together. After 24 hours the solution containing AmberSep contained 0.94 mM iodide, meaning 53% of the iodide had been removed. After 24 hours the solution containing AmberLite contained 0.62 mM iodide, meaning 69% of the iodide had been removed.

[0428] The iodide loaded resins were filtered from the solutions and rinsed with DI water. They were then each placed in separate bottles with 50 mL of 0.2 M KCl. The two bottles were shaken for 24 hours to mix the solutions and resins together. After 24 hours the solution containing AmberSep contained 2.0 mM iodide, meaning 17% of the initial iodide had been recovered. The solution containing AmberLite contained 1.91 mM iodide, meaning that 16% of the initial iodide had been recovered.

[0429] As used herein, the terms “substantially” or “generally” refer to the complete or near complete extent or degree of an action, characteristic, property, state, structure, item, or result. For example, an object that is “substantially” or “generally” enclosed would mean that the object is either completely enclosed or nearly completely enclosed. The exact allowable degree of deviation from absolute completeness may in some cases depend on the specific context. However, the nearness of completion will be so as to have generally the same overall result as if absolute and total completion were obtained. The use of “substantially” or “generally” is equally applicable when used in a negative connotation to refer to the complete or near complete lack of an action, characteristic, property, state, structure, item, or result. For example, an element, combination, embodiment, or composition that is “substantially free of” or “generally free of” an element may still actually contain such element as long as there is no significant effect thereof.

[0430] In the foregoing description, the inventions have been described with reference to specific embodiments. However, it may be understood that various modifications and changes may be made without departing from the scope of the inventions.

## Claims

1.-20. (canceled)

21. A method of PFAS destruction comprising: adding a sulfite salt and an iodide or a bromide salt to an aqueous solution containing PFAS; and then irradiating the aqueous solution with light at 222 nm.

22. The method of claim 21 wherein the halide salt is an iodide salt.

- 23.** The method of claim 22 where the iodide concentration in the aqueous solution containing PFAS is between 0.1 mM and 50 mM after adding the iodide salt.
- 24.** The method of claim 21 wherein the halide salt is a bromide salt.
- 25.** The method of claim 24 where the bromide concentration in the aqueous solution containing PFAS is between 5 mM and 150 mM after adding the bromide salt.
- 26.** The method of claim 21 further comprising, prior to irradiating the aqueous solution including PFAS, adding a carbonate to the aqueous solution including PFAS.
- 27.** The method of claim 21 wherein irradiating the aqueous solution destroys greater than about 99% of the PFAS in the solution.
- 28.** The method of claim 21 wherein irradiating the aqueous solution destroys greater than about 99.9% of the PFAS in the solution.
- 29.** The method of claim 21 further comprising adding a base to the aqueous solution containing PFAS in an amount sufficient to raise a pH of the aqueous solution including PFAS to about 10 or more.
- 30.** The method of claim 29 wherein the halide salt is an iodide salt.
- 31.** The method of claim 30 where the iodide concentration in the aqueous solution containing PFAS is between 0.1 mM and 50 mM after adding the iodide salt.
- 32.** The method of claim 29 wherein the halide salt is a bromide salt.
- 33.** The method of claim 32 where the bromide concentration in the aqueous solution containing PFAS is between 5 mM and 150 mM after adding the bromide salt.
- 34.** A method of PFAS destruction comprising: adding a sulfite salt and an iodide or a bromide salt to an aqueous solution containing PFAS; and then irradiating the aqueous solution containing PFAS with a light source comprising a krypton/chloride excimer lamp.
- 35.** The method of claim 34 wherein the halide salt is an iodide salt.
- 36.** The method of claim 34 wherein the halide salt is a bromide salt.
- 37.** The method of claim 34 wherein the light source comprises a plurality of krypton/chloride excimer lamps.
- 38.** The method of claim 37 wherein irradiating the aqueous solution containing PFAS comprises providing the plurality of krypton/chloride excimer lamps each lamp having an electrical energy of 100 Watts or greater.
- 39.** The method of claim 34 further comprising, prior to irradiating the aqueous solution containing PFAS, adding a base to the aqueous solution containing PFAS in an amount sufficient to raise a pH of the aqueous solution containing PFAS to about 1 or more.
- 40.** The method of claim 39 wherein the halide salt comprises an iodide salt.
- 41.** The method of claim 39 wherein the halide salt comprises a bromide salt.
-
