(57) **ABSTRACT**

An object of initial unknown position on a map may be determined by traversing through moving and turning to establish motion trajectory to reduce its spatial uncertainty to a single location that would fit only to a certain map trajectory. An artificial neural network model learns from object motion on different map topologies may establish the object's end-to-end positioning from embedding map topologies and object motion. The proposed method includes learning potential motion patterns from the map and perform trajectory classification in the map's edge-space. Two different trajectory representations, namely angle representation and augmented angle representation (incorporates distance traversed) are considered and both a Graph Neural Network and an RNN are trained from the map for each representation to compare their performances.

(Continued)

The results from the actual visual-inertial odometry have shown that the proposed approach is able to learn the map and localize the object based on its motion trajectories.

SYSTEMS, METHODS AND DEVICES FOR MAP-BASED OBJECT'S LOCALIZATION DEEP LEARNING AND OBJECT'S MOTION TRAJECTORIES ON GEOSPATIAL MAPS USING NEURAL NETWORK

RELATED APPLICATION

The present application is a U.S. national stage entry of International Application No. PCT/US2021/040454, filed on Jul. 6, 2021, which claims priority to and the benefit from U.S. Provisional Patent Application Ser. No. 63/049,005 entitled "Systems, Methods and Devices For Map-Based Object Localization Using Deep Learning", filed on Jul. 7, 2020, and U.S. Provisional Patent Application Ser. No. 63/064,656 entitled "Systems, Methods and Devices For Learning Objects' Motion Trajectories On Maps Using Deep Learning For Temporally consistent Geo-Localization", filed on Aug. 12, 2020, the contents of which are herein incorporated by reference in their entirety for all purposes.

TECHNICAL FIELD

This disclosure generally relates to systems, methods, and devices for map-based object localization deep learning and object's motion trajectories on geospatial maps using neural networks.

BACKGROUND

Without the loss of generality, object localization can be defined as finding where an object is on a map given sensory data. Object localization is important and necessary for not only core applications, like robotics and autonomous ground and aerial vehicles, but also tracking of pedestrians for surveillance or health reasons. Despite advances in the field, localization is still a challenging problem especially when Global Positioning System (GPS) data is contested, such as degraded or not available.

The most popular positioning or localization technology for the outdoor environment is GPS, which utilizes georeferenced satellite constellation to estimate the object's location (Hofmann-Wellenhop et al., 2012). However, the limitations are also notable: GPS is not accurate for especially civilian and consumer applications, and the signal suffers from multi-path problems and may be unavailable or unreliable in several areas, such as underground, in tunnels, indoors, urban canyons and in planetary missions. To resolve these limitations, researchers have proposed Indoor Positioning Systems (IPS) (Mautz, 2012) to localize objects using installed infrastructure, such as WiFi, Bluetooth, UltraWide Band (UWB), etc. Despite being a fast growing research area, IPS technology using external signals requires large investment and has high maintenance cost.

SUMMARY

In an embodiment, a method for generating object positioning is discussed, the method including: in response to receiving motion based relative position signals $\{s_1, s_2 \dots s_n\}$ generated from the at least one device of an object that traverses within a map M, wherein the map M is represented as a graph G, including a plurality of nodes $V=\{v_1, v_2 \dots v_n\}$ and a plurality of edges $E=\{e_1, e_2 \dots e_n\}$, wherein: each of the nodes $\{v_1, v_2 \dots v_n\}$ is assigned with a unique identification which represents a place and other features attributed to that place at a certain time sequence, and each

2

of the edges $\{e_1, e_2 \dots e_n\}$ is assigned with a unique identification which represents a traversable path between the nodes.

An algorithm stored in a memory may be executed by a processor, in the at least one device of the object to perform steps, including: (a) extracting, by the processor of the at least one device of the object, the motion based relative position signals $\{s_1, s_2 \dots s_n\}$ generated from the at least one device of the object to obtain time sequenced edges $\{e_{i-1}, e_i, e_{i+1}, e_{i+2} \dots\}$ and nodes $\{v_{i-1}, v_i, v_{i+1}, v_{i+2} \dots\}$ information traversed by the object at time t at node v_i , such that the object at the at node v_i either makes a turn or continues to move in one direction, wherein the node v_i is associated with a distance l_i traversed and a turning angle ϕ_i which represents directional information formed at the node v_i between a previous edge e_{i-1} and a next edge e_{i+1} of the object has traversed; (b) generating, by the processor, a relative motion trajectory T_r of the object over n nodes $\{v_1, v_2 \dots v_n\}$ from one or both of n-1 distances $\{l_1, l_2 \dots l_{n-1}\}$ and n-2 turning angles $\{\phi_1 \dots \phi_{n-2}\}$ computed from the motion based relative position signals $\{s_1, s_2 \dots s_n\}$; (c) quantizing the n-2 turning angles $\{\phi_1 \dots \phi_{n-2}\}$ to identify a given discrete bin for each relative motion trajectory T_r at the time t from a plurality of discrete bins; (d) training a neural network model that maps the graph G to an embedding space Z based on object traversable edges $\{e_1, e_2 \dots e_n\}$ and nodes $\{v_1, v_2 \dots v_n\}$ to learn object's motion trajectories j on the map M; and (e) generating a geolocation A_x of the object according to the trained neural network within the map M and the embedding space Z.

In another embodiment, a method for determining object motion trajectories is discussed, the method including: in response to receiving motion based sequence of discrete distances and directions of object's trajectories at time t generated from at least one device of an object that traverses within a topological map M, executing by a processor, an algorithm stored in a memory of the at least one device of the object to perform steps, including: determining a geolocation probability P_{loc} of an object according to a sequence of discrete distances and directions of object's trajectories at time t, wherein the geolocation probability P_{loc} of the object's motion trajectories as equation (1):

$$P_{loc}=P(s_t|\phi,\beta_{1..n},M) \quad (1)$$

where, s_t is an output edge id, and the P_{loc} indicates an output result conditioned on the topological map, M, and the sequence of direction with a turning angle ϕ at a node and a distance β between nodes, where t is time sequence.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1A illustrates a trajectory of an object traveling within a topological map from one geolocation to another geolocation.

FIG. 1B illustrates a motion trajectory representation using local turning angles and distances.

FIG. 1C illustrates a visual inertial odometry (VIO) which is used for motion data collection and processing.

FIG. 2 illustrates a neural machine translation network with attention mechanism for predicting accuracy rate in future steps based on an input sequence.

FIG. 3 illustrates an example of pipeline processing by an Artificial Neural Network (ANN) model for generation of a sequence of motion features used in motion and object location learning.

FIG. 4 illustrates a structure of an RNN cell.

FIG. 5 illustrates a structure of an LSTM cell.

FIG. 6 illustrates a Recurrent Neural Network (RNN) which is used for processing input sequence to generate a trajectory of a traveling object.

FIG. 7 illustrates an example of inconsistent edge localization.

FIGS. 8A and 8B illustrate two different strategies to deal with temporal consistency.

FIG. 9 illustrates a visual odometry pipeline for motion trajectory generation.

DETAILED DESCRIPTION

Studies show that positioning and navigation in mammals rely on the ability to form neural maps of the environmental space. Recent studies on biological systems have revealed that navigation system consists of several specialized cells (place cell, grid cell, head direction cell, and border cell etc.) which collectively form a map representation of space that not only operates in the present but also can be stored as a memory for later use. The disclosure mimics a concept of map-like representation of place in the brain “cognitive map” or specialized neural networks that enable animals to navigate and find its position in an environment.

Stimuli that help humans to achieve positioning on a map, for instance a blind person or in deep dark night, is based on the distances they traversed and corners they turned. A simple example would be getting directions for an unknown location from others, e.g., “to get to the grocery, go straight 100 meters (moving) and turn left (turning)”.

An object of initial unknown position on a map may be determined by traversing through moving and turning to establish motion trajectory to reduce its spatial uncertainty to a single location that would fit only to a certain map trajectory. In the disclosure, the method or algorithm may use a topological map-based approach using motion trajectory as training data to achieve self-localization is developed. Formally, given a sequence of distances and turning angles along with a map, the method or algorithm may sequentially predict which edge is located. In fact, the movement of object on a graph may be physically constrained by the condition of the topology of an underlying road network.

In order to guarantee a connectivity of edge prediction, the method or algorithm may adopt hypotheses generation and pruning strategy. Moreover, due to distance information needed, the approach requires that absolute scale of motion trajectory which may directly lead to employing stereo visual odometry method to obtain motion trajectory.

The following sections describe how this process may be done. Firstly, topological map-based geolocation process may be proposed through trajectory learning, including map representation, motion trajectory representation and (artificial) neural network architecture. Then, two different strategies may be used to deal with temporal consistency of location. Lastly, a visual odometry method on how to obtain metric motion trajectory may be proposed.

More specifically, the two different approaches to determine the object’s location and its trajectory may include: Recurrent Neural Network (RNN) and Graph Neural Network (GNN). Both projects the map and the motion into an embedding space Z . RNN has a recursive structure that implicitly models the motion information. The GNN has a message passing strategy that defines the motion of the object on the map.

A Graph Neural Network (GNN) based model or a Recurrent Neural Network (RNN) model may learn from an object’s trajectory motion on different map topologies and

may establish the object’s end-to-end localization from mapping topologies. The proposed method includes learning potential motion patterns from the map and perform trajectories classification in the map’s edge-space. Two different trajectories representations, namely angle representation and augmented angle representation (incorporates distance traversed) are considered and the RNN is trained from the map for each representation to compare their performances. The results from the actual visual-inertial odometry have shown that the proposed approach is able to learn the map and localize the object based on its motion trajectories. Hence, a general pipeline (to be discussed in FIGS. 3 and 4) for generating a sequence of motion features may be used in motion learning and retrieving the object location.

FIG. 1A illustrates an OpenStreetMap (OSM) representation motion trajectory **102** of an object traveling within a topological map M from one geolocation A_1 to another geolocation A_2 . FIG. 1B illustrates the motion trajectory **102** representation of the object generated as a result of object’s motion on the topological map M which consists of a sequence of distances $\{l_1, l_2 \dots l_n\}$ (i.e., $l_1, l_2 \dots l_{n-1}$) traversed and local turning angles $\{\phi_1 \dots \phi_n\}$ (i.e., $\phi_1 \dots \phi_{n-2}$) taken. In an example, the map M may be represented as a graph G , including a plurality of nodes $V=\{v_1, v_2 \dots v_n\}$ and a plurality of edges $E=\{e_1, e_2 \dots e_n\}$, wherein: each of the nodes $\{v_1, v_2 \dots v_n\}$ is assigned with a unique identification which represents a place and other features attributed to that place at a certain time sequence t , and each of the edges $\{e_1, e_2 \dots e_n\}$ is assigned with a unique identification which represents the traversable path (i.e., trajectory **102**) between the nodes V_0 (geolocation A_1) and v_5 (geolocation A_2).

FIG. 1C illustrates at least one device (e.g., visual inertial odometry (VIO) device **100**) which may be used for generating and processing motion based relative position signals $\{s_1, s_2 \dots s_n\}$ which include time sequenced edges $\{\dots e_{i-1}, e_i, e_{i+1}, e_{i+2} \dots\}$ and nodes $\{\dots v_{i-1}, v_i, v_{i+1}, v_{i+2} \dots\}$ traversed by the object on the map M to determine and learn its geolocation or motion trajectory as shown in FIG. 1B. In an example, the VIO device **100** may include a mobile smart phone **120**. Visual inertial odometry is a process of estimating the pose (position and orientation) of the object using both a camera **121** and an inertial measurement unit (IMU) **122** on the VIO **100** that measures two dimensional (2-D) or three dimensional (3D) accelerations and orientation by a gyroscope. An open source mobile smart-phone application **120c** may be developed for collecting synchronized video data **123** and IMU data **124** (3 acceleration and 3 angular velocity).

In other examples, the VIO device **120** may also include a Light Detection and Ranging (LIDAR) structured light sensors (depth sensors) or a sound navigating ranges (SONAR) (under water depth sensors). In an example of the method, the motion based relative position signals are generated in two-dimensional (2-D) having one angle and one distance, or in three-dimensional (3-D) space having two angles (e.g., with z axis and polar coordinates) and two distances.

In implementation, in response to receiving motion based relative position signals $\{s_1, s_2 \dots s_n\}$ generated by the VIO device **120** that traverses within the map M , a processor **120b** of the VIO device **120** may execute an algorithm stored in a memory **120a** to perform steps, including: (a) extracting the generated motion based relative position signals $\{s_1, s_2 \dots s_n\}$ of the object to obtain time sequenced edges $\{\dots e_{i-1}, e_i, e_{i+1}, e_{i+2} \dots\}$ and nodes $\{v_{i-1}, v_i, v_{i+1}, v_{i+2} \dots\}$ information traversed by the object at time t at

5

node v_i , such that the object at the at node v_i either makes a turn or continues to move in one direction, wherein the node v_i is associated with a distance l_i traversed and a turning angle ϕ_i which represents directional information formed at the node v_i between a previous edge e_{i-1} and a next edge e_{i+1} of the object has traversed; (b) generating, by the processor **120b**, a relative motion trajectory T_r of the object over n nodes $\{v_1, v_2 \dots v_n\}$ from one or both of $n-1$ distances $\{l_1, l_2 \dots l_{n-1}\}$ and $n-2$ turning angles $\{\phi_1 \dots \phi_{n-2}\}$ computed from the motion based relative position signals $\{s_1, s_2 \dots s_n\}$; (c) quantizing the $n-2$ turning angles $\{\phi_1 \dots \phi_{n-2}\}$ to identify a given discrete bin for each relative motion trajectory T_r at the time t from a plurality of discrete bins; (d) training a neural network model that maps the graph G to an embedding space Z based on object traversable edges $\{e_1, e_2 \dots e_n\}$ and nodes $\{v_1, v_2 \dots v_n\}$ to learn object's motion trajectories j on the map M ; and (e) generating a geolocation A_x of the object according to the trained neural network within the map M and the embedding space Z .

As shown in FIG. 1C, sensor fusion may be performed by open-source VINS-Mono approach (Qin et al., 2018) that provides high-accuracy visual inertial odometry in the form of three rotation and three position data **132** with relative scale information.

FIG. 2 illustrates a Neural Machine Translation (NMT) network **200** with attention mechanism **220** may be used to predict accuracy rate in future steps based on an input training data, such as feature sequence: $X=(\phi_1, \phi_2, \dots \phi_n)$ (where $\phi_i \in \mathbb{R}$, ($i=1, 2 \dots n$), n is a length of sequence, and ϕ_i is i th angle, wherein $l_1, l_2 \dots l_{n-1}$ are distances of the sequence) which feature sequence X is the motion based relative position signals $\{s_1, s_2 \dots s_n\}$ extracted from trajectories consisting of n nodes. Based on a format of input and output training data, a sequence-to-sequence model may be implemented to predict an accuracy rate in future steps. This model takes a sequence of features X and produces another sequence with encoder-decoder mechanism where encoder and decoder are both Recurrent Neural Network (RNN). An attention mechanism over the encoder Long Short Term Memory (LSTM) states may provide a random access memory to source hidden states that can be accessed throughout the translation process. In another embodiment, the input sequence of features X are not limited only to the extracted features from motion based relative position signals, they may be words and letters from written script or speech.

In an example, there may be three types of input training data sequence formed, namely, angle sequence (range between 0 and π), length sequence l , and angle-length sequence combining both angle and length. The training may include: (a) reducing the computational complexity by quantizing the angle ϕ_i into 72 bins (2.5° bin size), (b) map the quantized angle values between $[0, 1]$, i.e., normalization, and extends 72 bins to 1001 bins in improving prediction accuracy in equation (2):

$$\phi_{normalized} = \frac{\phi_{original} - \phi_{min}}{\phi_{max} - \phi_{min}}, \quad (2)$$

and (c) perform preprocessing on unique edge lengths with ordered integers such as 1, 2 and 3, and normalize while keeping same three decimals resolution in equation (3):

$$l_{normalized} = \frac{l_{original} - l_{min}}{l_{max} - l_{min}}. \quad (3)$$

6

FIG. 3 illustrates an example of pipeline processing **300** by an Artificial Neural Network (ANN) model for generation of a sequence of motion features used in motion and object location learning. The box **330** in FIG. 3 is an Artificial Neural Network (ANN) model, such as recurrent neural network (RNN) or Graph Neural Network (GNN), that learns how objects move on different map topologies to establish an end-to-end object geolocation positioning. The techniques described here includes learning motion patterns from the map and perform positioning as trajectory classification in the map's edge-space.

Borrowed from mammal navigation system, the trajectory is converted into a feature space constructed of two different trajectory representations, namely angle representation (direction cell in brain) and augmented representation based on incremental distances (grid cell). These features (i.e., edge space and angle) are input to an ANN model, such as RNN or GNN, for training. The results generated from the developed system that uses real-world visual-inertial odometry have shown that the proposed biomimetic approach is able to position objects on a map based on their motion trajectories.

Referring to FIG. 3, the location learning may be performed by the following functional blocks. In block **310**, step 1, a map M may be represented as a graph G with a plurality of nodes $V=\{v_1, v_2 \dots v_n\}$ and edges $E=\{e_1, e_2 \dots e_n\}$, wherein: each of the nodes $V_1, v_2 \dots v_n$ is assigned with a unique identification which represents a place, and each of the edges $e_1, e_2 \dots e_n$ is assigned with a unique identification which represents a traversable path.

In an example, the at least one map is generated from inputs from one or a combination of: a blue print, a fixed image picture, a Geographic Information System (GIS), an OpenStreetMap (OSM), A CAD model, or an underwater topographical map. The graph node's may carry features such as the geo-coordinates, centrality, place, category etc. The graph edge may carry features such as length, the orientation, and the traffic information etc.

In step 2, motion trajectory representation may be established. The motion trajectories are encoded as a sequence of motion features generated as the object either makes a turn or continues to move in a straight direction; extracting, by a processor of the object, motion based relative position signals generated from at least one device of the object, wherein the motion based relative position signals comprise time sequenced edges and nodes traversed by the object on the at least one map, wherein each node is associated with a turning angle ϕ_i which represents directional information formed at the node), between a previous edge e_{i-1} and a next edge e_{i+1} of the object has traversed; generating, by the processor of the object, a relative motion trajectory of the object over n nodes $\{v_1, v_2 \dots v_n\}$ from one or both of $n-1$ distances $\{l_1, l_2 \dots l_{n-1}\}$ and $n-2$ turning angles $\{\phi_1 \dots \phi_{n-2}\}$ computed from the motion based relative position signals; quantizing the $n-2$ turning angles $\phi_1 \dots \phi_{n-2}$ to identify a given discrete bin from a plurality of discrete bins for each relative motion trajectory. In an example, the method may include using the at least one device **100** (see FIG. 1C) that generates motion based relative position signals of the object.

In steps 3 and 4, the ANN model may require training the model to learn object motion trajectories on the at least one defined map, which is then used to estimate the geolocation of the object on the at least one defined map according to the trained neural network. In an example of the model, the trained neural network that embeds the map graph on a multi-dimensional manifold may include a GNN model or

an RNN model that may have layers of neurons having feedback loops **302** for processing one-time sequenced edge and node at a time to learn a location of the object on the at least one map.

Given an object trajectory fusion of visual and inertial sensors (see VIO **100** in FIG. **1C**) may be used to generate a trajectory j , a motion feature sequence X may be generated by quantizing turning angles and the distances traversed. Using this sequence X , the position of the object may be defined as the edge e_i connected to the last node visited v_{i-1} . Therefore, the object localization problem becomes a variable-length sequential data classification problem in embedding. In an example, the embedding may be a nonlinear function f that learns the map M :

$f: X \rightarrow Y$, wherein input feature sequence: $X = (\phi_1, \phi_2, \dots, \phi_n)$, where $\phi_i \in \mathbb{R}$, ($i=1, 2, \dots, n$), n is the length of sequence and ϕ_i is i th angle or $X = \{l_1, l_2, \dots, l_{n-1}\}$; and an output position label:

$Y = e_i$, $e_i \in E$, where $E = \{e_1, e_2, \dots, e_k\}$ is the output label space, k is the number of edges in the topological map, and the function f is the trained RNN that learns the map M .

In an example, the RNN **400** (see FIG. **4**) may be composed of layers of neurons that have feedback loops and have the ability to process transient sequences. In an example, this RNN architecture may model the dependencies between the map nodes V_i, v_{i+1} , etc., hence preserves the transition of state between consecutive time steps. In the most general form, the RNN (see FIG. **4**) may be the function of time t that takes the current input x_t , the previous hidden state h_{t-1} and produces a new state h_t through a non-linear activation function f and g : the trained RNN that learns the location of the object on the at least one map M may be defined by past object state:

$$h_t = f(x_t, h_{t-1})$$

$$y_t = g(h_t)$$

In another embodiment, the trained GNN input sequence x_t at one instance a time t , and the output sequence y_t generated at each time instant t , would depend on all previous hidden states h_{t-1} inputs, the non-linear function f : and produces a new state through a non-linear activation function f and g :

$$h_t = f(W \cdot x_t + U \cdot h_{t-1} + b_h);$$

$$y_t = g(v \cdot h_t + b_y)$$

where, U, v, W are weight matrices. h_t and y_t are hidden output and final output, and b_h and b_y are bias terms.

The RNN network **400** is not only cyclic but deep which makes training a difficult problem as it causes gradient vanishing and gradient explosion, even when special algorithms such as backpropagation through time (BPTT) are used (Werbos et al., 1990). One solution or improvement that overcomes these shortcomings is the Long Short-Term Memory (LSTM) network **500** (Hochreiter, Schmidhuber, 1997) in FIG. **5**, which use internal cyclic mechanisms called gates that overcome gradient vanishing problem, wherein each angle in the sequence generated by a preprocessing phase is fed into the LSTM network **500** one by one (see FIGS. **8A** and **8B**). These gates illustrated in FIG. **5** include forget gate f_t , input gate i_t and output gate o_t where, x_t is the input in time t . W and b represent weight matrices and bias terms for each gate. c_t and h_t are the LSTM cell output.

FIG. **6** illustrates a Recurrent Neural Network (RNN) with multiple outputs, which is used for processing input sequence to generate a trajectory of a traveling object. Trajectory localization problem can be thought of having three degree of freedom (DoF) (x, y, z). The use of the RNN in FIG. **6** may reduce the three degree of DoF complexity into one DoF due to the use of a sequence of turning angles at nodes. Each angle in the sequence generated by the preprocessing phase may be fed into the LSTM network cells **610a-610n**, one by one as shown in FIG. **6**. An embedding layer **430** may be attached to input layer **420a-420n** as a high-dimensional representation of discrete scalar input. The output **640a-640n** in each time step generates the edge **660a-660n** on which the object makes the last significant turn. A softmax function may be employed to calculate a probability of each output class which corresponds to a unique edge id in a given map graph using equation (4):

$$P(Y = i | y) = \text{softmax}(y) = \frac{e^y}{\sum_{j=0}^k e^y} \quad (4)$$

where z is the final linear output, and Y represents the output edge id which is equal to i .

To train the network, a negative log likelihood loss (NLL) on the edge probabilities may be performed using equation (5):

$$L_i = -\log(p_{yi}) \quad (5)$$

In another example, a topological map-based approach using motion trajectories j as training data may achieve self-localization. Formally, given a sequence X of distances $\{l_1, l_2, \dots, l_{n-1}\}$ and turning angles $\phi_1, \dots, \phi_{n-2}$ with a map M , one may sequentially predict which edge e_i may be located. However, the movement of object on graph G may be physically constrained by the fact of the topology of an underlying road network. In order to guarantee the connectivity of edge prediction, we adopt hypotheses generations and pruning strategy (see FIGS. **8A, 8B**). Due to distance information needed, our approach requires absolute scale of motion trajectories. This requirement directly leads us to employ stereo visual odometry method (see FIG. **9**) to obtain motion trajectories.

Main Method: 1. Motion Learning and Edge Localization: A mathematical model may be developed that encode biological system's treatment of spatial topological map for navigation and localization using neural network structure in a motion learning framework (see FIG. **2**). The proposed motion learning process utilizes motion on a given map in the form of a sequence of discrete distance and direction. Formally, given a map and a sequence of distance and direction information, an artificial neural network may be trained to solve the output edge location probability which is defined as follow:

$$P_{loc} = P(s_t | \phi, \beta_{1:t}, M)$$

where P_{loc} indicates the output result which is written as conditional probability. M is topological map and $\phi, \beta_{1:t}$ represents a sequence of direction and distance where t is the length of sequence. s_t is the output edge id.

FIG. **7** illustrates an example of inconsistent edge localization. Temporal Positioning Consistency: The motion learning process may take a sequence of trajectory features X as its input and its corresponding geolocations as output y_t to train the underlying neural network (e.g., RNN or GNN). The training process using this sequence implicitly

introduces temporal consistency to the estimated object positions. However, the output y_t may depend only on the past state h_{t-1} which may break the temporal consistency and that the sequence of output edge ids become inconsistent on the map.

An example of this undesired phenomena may be shown in FIG. 7, where the algorithm skips the (circled) dotted line 53 which is what should have been predicted and instead choosing two other wrong edges 46, 48 that are not connected; hence are temporally inconsistent.

In order to deal with this temporal inconsistency, it is proposed that two different multiple hypotheses generation and elimination strategies during the incremental localization as illustrated in FIGS. 8A, 8B.

Track hypothesis at time $T(T=1; 2 \dots t)$ are shown by H_t^i and $1 \leq i \leq n$ denotes the i^{th} hypothesis from among n hypotheses at time t . In each hypothesis, the light arrow denotes the edges connected to the edge denoting the current location hypothesis; the heavy bolded arrow refers to the selection of top k hypotheses with highest probability at time t . The two strategies change in the way they select the top k hypotheses.

A hypothesis at time $t-1$ may be defined as $\{H_{t-1}^i\}$ and a new hypotheses at time t may be defined as $\{h_t^{ij}\}$. A likelihood of the new hypothesis $\{H_t^{ij}\}$ may be defined by the likelihood ratio as equation (6):

$$P(H_t^{ij}) = \frac{P(H_t^i, H_{t-1}^j)}{P(H_{t-1}^j)}$$

where $i=1, \dots, n, j=1, \dots, n$ and n_1 and n_2 are the number of hypotheses in previous time and current time respectively.

Two strategies are similar as two different algorithms (Kruskal and Prim) in minimum spanning tree generation (MST).

Strategy 1 (Prim alike): first consider the connectivity and select top k edges. As shown in FIG. 8A, the algorithm generates a new location hypothesis at current time t for each edge connected to the previous edge defined by the hypothesis at time $t-1$. At $t=0$, all edges in the map are used to generate location hypotheses as we do not know where the object starts the traverse. In subsequent time instants, the probability of each of the hypotheses is computed by conditioning it on the previous location hypothesis. The number of hypotheses in this approach can be combinatorially explosive, hence, for computational reasons, one can keep only the top k location hypotheses. In an example, one may set $k=5$. Considering the way each hypothesis is generated based on the connectivity rule, temporal consistency of the location estimation is guaranteed.

Strategy 2 (Kruskal alike): first select top k edges and then consider the connectivity. As shown in FIG. 8B, the algorithm generates k location hypotheses with the highest probability based on the previous hypothesis at time $t-1$. The strategy proceeds by eliminating improbable hypotheses based on the edge connectivity constraint. While this method produces temporally consistent trajectories in the form of sequence of edges, it may suffer from the possibility that the true prediction might not be in the first top k hypotheses which may lead to an inconsistent prediction. Later in the experiments section, one may show results that illustrates such inconsistencies and compare them with the strategy 1.

FIG. 9 illustrates a visual odometry pipeline for motion trajectory generation. The distance information used as a

motion features may be encoded with the object's trajectory which may require to generate a metric trajectory by utilizing the visual odometry (see steps 902-904). The visual odometry may estimate a motion trajectory Tr with six degrees of freedom including 3D position and orientation of the platform using image data (see step 908). Visual odometry may estimate the relative motion trajectory from a single camera (monocular) setup or from a stereo camera setup. In this disclosure, a stereo setup with known calibration may be used. Using this information, one may estimate the relative rotation R and translation T by detecting and matching features between consecutive image frames. These matching points are then used in photogrammetric intersection framework to estimate instantaneous relative motion R and T (see steps 910-912), and may obtain a sequence of metric points as motion trajectory Tr .

The motion trajectory Tr is produced using the angle sequence as training data input X to RNN. The output data Y that corresponds to this training data are the edge ids on which the last turn occurs. The VINS-Fusion 130 (see FIG. 1c) may be used as the visual odometry approach to generate 3D trajectories.

The motion learning may be formulated as a conditional variable sequence prediction problem using RNN as shown in FIG. 6. The generated training trajectory dataset may be used to train the RNN where each input is a discrete angle ϕ_i and the output is corresponding edge id. Considering that learning the map M is a multi-class classification problem, at each time instant t , a cross-entropy function may be utilized as the loss function for measuring the training performance. One may choose a stochastic gradient descent as optimization method.

In FIG. 7, it was shown that the accuracy of localization as a function of length of trajectory segment. An accuracy of geolocation as a function of length of trajectories segment may be computed as using equation (7):

$$\text{Accuracy}(i) = \frac{1}{N} \sum_{j=0}^N T_{ji} \quad (7)$$

T_{ji} is correctness of prediction, $\{0, 1\}$, on i -th node of trajectories j and N is a total number of training trajectories used to generate a plot.

One should note that using the accuracy at the i -th node refers to the accuracy of having a trajectory of length i . It may be observed that the accuracy increases with increase in the length of trajectory from 1 to entire trajectory segment. Considering the input angle and output edge are mapped to each other, as vehicle traverses the map, the spatial uncertainty of its whereabouts reduces to a single location hypothesis. This observation is supported by the fact that the longer the trajectory becomes, it would fit only to a certain map location due to increase in accuracy.

While particular examples above have been illustrated and described herein, it should be understood that various other changes and modifications may be made without departing from the spirit and scope of the claimed subject matter. Moreover, although various aspects of the claimed subject matter have been described herein, such aspects need not be utilized in combination. Accordingly, it will be appreciated that the above described examples should not be construed to narrow the scope or spirit of the disclosure in any way. Other examples, embodiments, aspects, and advantages will become apparent from the following detailed description taken in conjunction with the accompanying

11

drawings. It is therefore intended that the appended claims cover all such changes and modifications that are within the scope of the claimed subject matter.

What is claimed is:

1. A method for generating object absolute positioning, comprising:

in response to receiving motion based relative position signals $\{s_1, s_2 \dots s_n\}$ generated by the at least one device of an object that traverses within a map M, wherein the map M is represented as a graph G, comprising a plurality of nodes $V=\{v_1, v_2 \dots v_n\}$ and a plurality of edges $E=\{e_1, e_2 \dots e_n\}$, wherein: each of the nodes $\{v_1, v_2 \dots v_n\}$ is assigned with a unique identification which represents a place and other features attributed to that place at a certain time sequence, and each of the edges $\{e_1, e_2 \dots e_n\}$ is assigned with a unique identification which represents a traversable path between the nodes,

executing by a processor, an algorithm stored in a memory of at least one device of the object to perform steps, comprising:

extracting, by the processor of the at least one device of the object, the motion based relative position signals $\{s_1, s_2 \dots s_n\}$ generated from the at least one device of the object to obtain time sequenced edges $\{ \dots e_{i-1}, e_i, e_{i+1}, e_{i+2} \dots \}$ and nodes $\{ \dots v_{i-1}, v_i, v_{i+1}, v_{i+2} \dots \}$ information traversed by the object at time t at node v_i , such that the object at the at node v_i either makes a turn or continues to move in one direction, wherein the node v_i is associated with a distance l_i traversed and a turning angle (which represents directional information formed at the node v_i between a previous edge e_{i-1} and a next edge e_{i+1} of the object has traversed;

generating, by the processor, a relative motion trajectory T_r of the object over n nodes $\{v_1, v_2 \dots v_n\}$ from one or both of n-1 distances $\{l_1, l_2 \dots l_{n-1}\}$ and n-2 turning angles $\{\phi_1 \dots \phi_{n-2}\}$ computed from the motion based relative position signals $\{s_1, s_2 \dots s_n\}$; quantizing the n-2 turning angles $\{\phi_1 \dots \phi_{n-2}\}$ to identify a given discrete bin for each relative motion trajectory T_r at the time t from a plurality of discrete bins;

training a neural network model that maps the graph G to an embedding space Z based on object traversable edges $\{e_1, e_2 \dots e_n\}$ and nodes $\{v_1, v_2 \dots v_n\}$ to learn object's motion trajectories j on the map M; and

generating a geolocation A_x of the object according to the trained neural network within the map M and the embedding space Z.

2. The method according to claim 1, wherein the trained neural network comprising a trained Graph Neural Network (GNN) model utilizing a message passing mechanism that fires neurons by processing the time sequenced edges $\{ \dots e_{i-1}, e_i, e_{i+1}, e_{i+2} \dots \}$ and nodes $\{ \dots v_{i-1}, v_i, v_{i+1}, v_{i+2} \dots \}$ at the time t_i to learn or estimate the geolocation A_x of the object on the map M.

3. The method according to claim 2, wherein the trained Graph Neural Network that learns or estimates the geolocation A_x of the object on the map M is defined by a non-linear function f:

f: $X \rightarrow Y$ based on the message passing mechanism, wherein X is an input feature sequence: $X=(\phi_1, \phi_2, \dots \phi_n)$ or $X=\{l_1, l_2 \dots l_{n-1}\}$, where $\phi_i \in \mathbb{R}$, ($i=1, 2 \dots n$),

12

n is a length of sequence, and ϕ_i is ith angle, wherein $l_1, l_2 \dots l_{n-1}$ are distances of the sequence;

wherein Y is an output position label: $Y=e_i, e_i \in E$, where $E=\{e_1, e_2 \dots e_n\}$ is the output label space, k is the number of edges in the at least one defined map.

4. The method according to claim 2, comprising using a softmax function:

$$P(Y = ilz) = \text{softmax}(z) = \frac{e^z}{\sum_{j=0}^k e^z}$$

to calculate a probability of each edge with a final output which corresponds to unique edge ID in a given map graph, where, z is the final linear output, $Y=i$ represents the edge ID and is equal to i.

5. The method according to claim 1, wherein the trained neural network comprising a trained Recurrent Neural Network (RNN) model comprising layers of neurons having feedback loops for processing one-time sequenced edge e_i and node v_i at the time t to learn or estimate the location A_x of the object on the map M.

6. The method according to claim 5, wherein the trained Recurrent Neural Network model processes the input sequence x_t at an instance of time t, and an output sequence generated at the time instant t depends on all previous hidden states h_{t-1} inputs, the non-linear function f, and produces a new state through a non-linear activation function f and g:

$$h_t = f(W \cdot x_t + U \cdot h_{t-1} + b_h);$$

$$y_t = g(V \cdot h_t + b_y)$$

where, U, V, W are weighted matrices, h_t and y_t are hidden output and final output, and b_h and b_y are bias terms.

7. The method according to claim 5, wherein the trained RNN further comprising a Long Short-Term Memory (LSTM) network or a transformer network which uses internal cyclic mechanisms and attention mechanisms, wherein each angle ϕ_i in the sequence generated by a preprocessing phase is fed into the LSTM network one by one.

8. The method according to claim 1, wherein the at least one device of the object that generates the motion based relative position signals $\{s_1, s_2 \dots s_n\}$ comprises one or a combination of: a fixed image camera, a video camera, a mobile smart phone, an inertial measurement unit (IMU), a Light Detection and Ranging (LIDAR) structured light sensors (depth sensors) or a sound navigating ranges (SONAR) (under water depth sensors) that measure two dimensional (2-D) or three dimensional (3D) accelerations and gyroscope, a visual inertial odometer.

9. The method according to claim 1, further comprising using one or both of distances $\{l_1, l_2 \dots l_{n-1}\}$ between nodes or augmented angle representation in the turn angle ϕ_i to improve accuracy, wherein the motion based relative position signals $\{s_1, s_2 \dots s_n\}$ are generated in two dimensional (2-D) and three dimensional (3-D) space.

10. The method according to claim 1, wherein the map M is generated from inputs from one or a combination of: a blue print, geographical information system, a fixed image picture, motion images, an OpenStreetMap (OSM), Simultaneous Localization and Mapping (SLAM), Global Positioning System (GPS), Indoor Positioning System (IPS), under water topographical map and visual Odometry (VO).
